Preface

From their continued appearance in art and culture to their savoured place at the dinner table, scallops have not lost their general appeal and continue to garner the attention of scientists, aquaculturists, chefs, shell collectors and others. Discussion during the 6th International Pectinid Workshop in 1987 provided the impetus for the first edition of *Scallops: Biology, Ecology and Aquaculture* which was published in 1991 and has been out of print for nearly a decade. Talk of a second edition began almost immediately, but was gently ignored for some years because of the time and effort required of all contributors and a sense on the part of the original editor that there was not enough new information to warrant a second volume.

Interest in all aspects of scallop biology and ecology has continued to increase, culture efforts have expanded globally and scallops continue to bring high prices from both the commercial fisheries and aquaculture ventures.

Potential authors began to inquire enthusiastically about the potential for a second edition, Elsevier Science Publishers were eager to add the volume to their series, and there was a renewed sense of need coupled with availability of new information to proceed with publishing a second edition.

The present volume represents an updated and revised version of the first edition. It is a comprehensive overview of the biology, ecology and aquaculture for scallop species worldwide. Some chapters have been completely rewritten by previous or new authors and two chapters have been reprinted as in the original volume (Chapter 5 - Neurobiology and Behaviour of the Scallop by Wilkens and Chapter 8 - Physiological Integrations and Energy Partitioning by Thompson and MacDonald) as they are as pertinent now as they were in 1991. Other chapters have been revised and new ones added (Nutrition and accounts by country of aquaculture and fisheries – Brazil, Venezuela and the Russian Federation now that the former Soviet Union has transformed since the first edition!).

This work would not have been possible without the assistance of several individuals. We thank Linda Kallansrude, Manon Chouinard and Dinah Helpert who provided secretarial and administrative support, Maille Lyons who took on the arduous task of developing the indices, Mara Vos-Sarmiento (Elsevier) for assistance, guidance and support and a special thanks to Sharon, Christopher, Michael and Max for their support and patience.

Finally, the authors are to be congratulated for their efforts and thanked profusely for their patience during the publication process.

We have dedicated this volume to Sam Naidu, friend and colleague, who devoted his career to working with fishermen, aquaculturists and government managers to ensure a sustainable fishery for future generations. Sam was a gentleman, generous with his knowledge and expertise, accepted no social barriers and was a pillar of the Pectinid Workshops. Moreover, he had perfected the art of living well and appreciating life.

Since publication of the first edition, there have been seven subsequent International Pectinid Workshops, the 15th recently held in Mooloolaba, Australia and the 16th planned for Halifax, Nova Scotia, Canada in 2007.

We hope this volume will continue to foster interest in scallops, especially aquaculture for a sustainable future, for years to come.

Sandra E. Shumway and G. Jay Parsons
Groton, Connecticut Ottawa, Ontario

Preface from First Edition

Scallops are among the better known shellfishes and are widely distributed throughout the world. They are of worldwide economic importance and support both commercial fisheries and mariculture efforts. They have been the subject of numerous research efforts and their high economic stature encourages aquaculture efforts by both academicians and industrial researchers. The rapid growth, early maturity and high economic value of many scallop species offer special inducement to mariculturists. Scallops are already cultured successfully in a number of geographic locations and emphasis is increasing globally. Further, scallops play an important role in the structure and function of the communities of which they are a characteristic and important component.

Not since the publication of *Marine Mussels* (Bayne, 1975: IBP Handbook) has the current knowledge of a particular group of molluscs received a comprehensive coverage. His effort was a welcome addition to the scientific literature and provided an opportunity to synthesise a wealth of information. For successful culture and management, a good knowledge of the biology of the species is necessary. While scallops have been the subject of a considerable amount of research, to date no integrated account exists of the biology.

Discussions regarding the need for a comprehensive treatise on scallops first took place in 1987 during the 6th International Pectinid Workshop in Menai Bridge, Wales. The level of enthusiasm was high and convincing the individual authors to undertake writing the chapters was an easy task. The subsequent task of collecting and integrating those manuscripts proved to be considerably more arduous. There were further discussions regarding the final versions of manuscripts during the 7th International Pectinid Workshop held in Portland, Maine in 1989. These meetings provided a unique opportunity for specialists in the field of scallop biology representing over 20 countries to meet and discuss their individual views and I believe that the final product has benefited greatly from those open and often lively discussions.

The present volume presents a comprehensive overview of the biology, ecology and aquaculture prospects, both present and future, for scallops worldwide. Although the subject matter is specifically concerned with the biology, ecology and aquaculture of scallop species, the book should be of interest and relevance to a number of readers including advanced undergraduate/graduate students, mariculturists and research workers. Contributed chapters have been prepared by some of the foremost authorities in their respective fields and represents some 18 countries. Manuscripts submitted by authors whose first language is not English have been corrected for gross grammatical errors and clarity of presentation only. Their efforts to write a manuscript in a foreign language are to be applauded and should not be clouded by editorial license.

The book is divided into two main sections, the first dealing with general biology, ecology and physiology and the second dealing with fisheries and culture efforts in specific countries. Obviously, scallops are of more economic importance in some countries than in others and this is reflected in the specific coverage of specific species in Chapter 12.

The phylogenetic relationship of scallop species of commercial interest are examined by Waller in Chapter 1. The available information on larval requirements and ranges of

tolerance of environmental variables, both prime importance to aquaculture efforts, are discussed by Cragg and Crisp in Chapter 2. Beninger and LePennec provide an elegant account of the internal anatomy of scallops in Chapter 3. The importance of scallop adductor muscles to the field of muscle physiology is clearly defined by Chantler in Chapter 4. Energy acquisition and utilisation are discussed by Bricelj and Shumway in Chapter 5 and the physiological integrations and partitioning of this energy are discussed in Chapter 6 by Thompson and MacDonald. Reproductive biology, another area of prime importance to culturists, is reviewed by Barber and Blake in Chapter 7. Two of the most striking features of scallops, eyes and their ability to swim, are discussed by Wilkens in Chapter 8: Neurobiology and Behavior. Diseases and parasites, major threats to aquaculture ventures, are discussed by Getchell in Chapter 9 and Gould and Fowler review the effects of pollutants on the commercial species of scallops in Chapter 10. General ecology, distribution and behavior are given in Chapter 11 by Brand. Beaumont and Zouros review the application of genetic tools to scallops and the importance of genetics to fisheries and aquaculture of scallops in Chapter 12. In Chapter 13, Orensanz, Parma and Iribane discuss population dynamics and the management of natural stocks. The commercial species of scallops are covered in Chapter 14 according to geographic location. Much of the data presented in Chapter 14 is being reported for the first time, including such elementary measures as growth, meat weight and landings.

This work would not have been possible without the efforts of Dr. Scott Siddall. His expertise in the field of desktop publishing coupled with his knowledge of shellfish biology made my task possible. His continued interest, support and interjections of humour when most needed made the task enjoyable. Jan Barter, Martha Hernandez-Davis, John Hedley and Jim Rollins helped in various ways and their willingness to undertake such arduous tasks as proofreading, crosschecking references, retyping of manuscripts and redrawing and repair of submitted diagrams are gratefully acknowledged. A special thanks must go to Bob Goodman, Elsevier Science Publishing Company, for his considerable patience in 'meeting' deadlines and his insight and support. Finally, I would like to thank the authors for their skill, patience and perseverance.

Appendix.....	43

Chapter 2. Development, Physiology, Behaviour and Ecology of Scallop Larvae

Simon M. Cragg

2.1 Introduction.....	45
2.2 Scallop life history characteristics	45
2.3 Larval development	55
2.3.1 Embryogenesis.....	55
2.3.2 Development of the larval shell	56
2.3.3 Organogenesis.....	59
2.3.3.1 Development of ciliation, the prototroch and the velum.....	59
2.3.3.2 Larval mantle	64
2.3.3.3 Musculature	64
2.3.3.4 Digestive tract.....	68
2.3.3.5 Sense organs	68

2.3.3.6 Apical organ	68
2.3.3.7 Statocysts	73
2.3.3.8 Eye spots	73
2.3.3.9 Mantle ciliation	74
2.3.3.10 Foot	77
2.3.3.11 Nervous system	78
2.3.3.12 Other organs	79
2.3.4 Metamorphosis	79
2.4 Comparative anatomy	81
2.5 Functional morphology	84
2.5.1 Locomotion	84
2.5.2 Feeding	85
2.5.3 Respiration	85
2.5.4 Sensory reception	86
2.6 Physiology and effects of environmental variables	87
2.6.1 Energy reserves and feeding	87
2.6.2 Respiration	88
2.6.3 Growth	89
2.6.4 Biochemical events during metamorphosis	90
2.7 Behaviour and larval distribution	90
2.7.1 Characteristics of locomotion during larval development	90
2.7.2 Responses to stimuli	91
2.7.3 Distribution of larvae	94
2.7.4 Development and the larval environment	98
2.7.5 Tolerance of environmental variables	99
2.8 Rearing methods	101
2.8.1 Spawning and manipulation of zygotes	101
2.8.2 Feeding	102
2.8.3 Control of disease in cultures	103
2.8.4 Collection of spat from wild stocks	104

Chapter 3. Structure and Function in Scallops

Peter G. Beninger and Marcel Le Pennec

3.1 Introduction	123
3.1.1 An overview of the scallop body	123
3.2 The mantle and its derivatives	126
3.2.1 Gross functional anatomy	127
3.2.2 Microanatomy and functions	130
3.3 Pallial organs and particle processing	132
3.3.1 Gills	132
3.3.1.1 Gill axis and arch	135
3.3.1.2 Principal filaments and dorsal expansion	135

3.3.1.3 Ordinary filament.....	137
3.3.1.4 Haemolymph circulation in the gill	141
3.3.1.5 Particle processing on the gill.....	141
3.3.1.6 Particle selection at the gill.....	141
3.3.1.7 Particle retention lower size limit	143
3.3.1.8 Ingestion volume regulation on the gill	143
3.3.2 Labial palps and lips	144
3.3.2.1 Labial palps.....	144
3.3.2.2 Particle processing on the labial palps.....	144
3.3.2.3 Lips.....	147
3.4 Digestive system and digestion.....	150
3.4.1 Mouth and oesophagus	150
3.4.2 Stomach, crystalline style and gastric shield.....	150
3.4.3 The digestive gland.....	154
3.4.4 Intestine, rectum and anus.....	157
3.4.5 Digestive sites and postingestive selection	159
3.5 Cardio-Vascular system	159
3.5.1 General circulation.....	160
3.5.1.1 The arterial system.....	160
3.5.1.1.1 Anterior aorta.....	160
3.5.1.1.2 Posterior aorta.....	160
3.5.1.2 The venous system.....	162
3.5.2 The heart.....	162
3.5.2.1 The ventricle	162
3.5.2.2 The auricles and their excretory structures	163
3.5.2.3 Structure and ultrastructure of heart cells	163
3.5.2.4 Contraction	165
3.5.2.4.1 Refilling.....	165
3.5.2.4.2 Coordination of alternate AV beat.....	166
3.5.2.4.3 Pacemaker mechanism	166
3.5.2.4.4 Regulation of pacemaker.....	167
3.5.3 Haemolymph.....	167
3.5.3.1 Plasma.....	168
3.5.3.2 Haemocytes	168
3.5.3.2.1 Haemocyte types	169
3.5.3.2.2 Functions of haemocytes	169
3.6 Excretory system.....	170
3.6.1 Pericardial (auricular) glands.....	170
3.6.2 Kidney	172
3.6.3 Functions of the kidney and pericardial glands.....	173
3.7 Reproductive system.....	173
3.7.1 Sexuality: Gonochory, hermaphroditism and their variants.....	173
3.7.2 Origin and formation of the gonad.....	176
3.7.3 Anatomy, histology and ultrastructure of the adult gonad	177

3.7.3.1 Outer epithelium	177
3.7.3.2 Perigonadal connective tissue	179
3.7.3.3 Inter-acinal connective tissue	179
3.7.3.4 Haemolymph sinuses	179
3.7.3.5 Acini	180
3.7.3.6 Evacuating ducts	180
3.7.4 Gametogenesis	180
3.7.4.1 Oogenesis	180
3.7.4.1.1 Premeiotic stage	180
3.7.4.1.2 Previtellogenic stage	181
3.7.4.1.3 Vitellogenesis and metabolite transport to the oocyte	181
3.7.5 Oocyte atresia	185
3.7.6 Spermatogenesis, spermatozoon ultrastructure and taxonomy	188
3.7.7 Fertilisation	190
3.8 Nervous and sensory systems	191
3.8.1 General organisation of the nervous system and functional anatomy of principal ganglia	191
3.8.1.1 Cerebral and pedal ganglia	191
3.8.1.2 The parietovisceral ganglion and its nerves	191
3.8.1.3 Histology and neurosecretions of the ganglia	196
3.8.1.4 The circumpallial nerve	198
3.8.2 Sensory structures	198
3.8.2.1 Visual system	198
3.8.2.2 Epithelial sensory cells and tentacles	198
3.8.2.3 Abdominal sense organ	199
3.8.2.4 Osphradia	201
3.8.2.5 Statoreceptors	204
3.8.3 Neurotransmitters and neurohormones	204
3.9 Foot-byssal complex	205
3.9.1 External morphology and development of the foot-byssal complex...	207
3.9.2 Anatomy and histology of the foot-byssal gland complex	208
3.9.2.1 The protein gland	208
3.9.2.2 The enzyme gland	208
3.9.2.3 The byssus	210
3.9.3 Functioning of the foot-byssal complex	210
Acknowledgments	210
References	211

Chapter 4. Scallop Adductor Muscles: Structure and Function

Peter D. Chantler

4.1 Introduction	229
4.2 Structure of the striated adductor muscle	231
4.2.1 Fibre microanatomy	231

4.2.2 Actin and thin filament structure	233
4.2.3 Thick filament structure	240
4.3 Structure of the smooth adductor muscle	243
4.3.1 Fibre microanatomy	243
4.3.2 Thin filament structure	245
4.3.3 The structure of paramyosin-rich thick filaments	247
4.4 Myosin	253
4.5 Function of the striated adductor	271
4.5.1 Mechanics	271
4.5.2 The interaction of myosin with actin	272
4.5.3 The crossbridge cycle	277
4.5.4 Myosin-linked regulation	282
4.6 Function of the smooth adductor	289
4.6.1 Physiology	289
4.6.2 Catch mechanism	292
4.7 Achievements and goals	296
Acknowledgments	298
References	298

Chapter 5. Neurobiology and Behaviour of the Scallop

Lon A. Wilkens

5.1 Introduction	317
5.2 The visual system	317
5.2.1 Functional anatomy of the eyes	317
5.2.2 Retinal physiology	322
5.2.3 Receptor potential biophysics	324
5.2.4 Anatomy and physiology of vision in the central nervous system	328
5.2.5 Visual behaviours	332
5.3 The locomotory system	335
5.3.1 Escape responses and swimming	335
5.3.2 Sensory and motor functions of the mantle	341
5.3.3 Innervation and neuromuscular physiology of the adductor muscle	345
5.3.4 Coordination of locomotory behaviour by the central nervous system	348
Acknowledgments	352
References	352

Chapter 6. Reproductive Physiology

Bruce J. Barber and Norman J. Blake

6.1 Introduction	357
6.2 Gametogenic cycles	358
6.2.1 Definition	358

6.2.2 Means of assessment.....	358
6.2.2.1 Visual observation	360
6.2.2.2 Gonad mass and index	360
6.2.2.3 Histology	367
6.2.2.4 Abundance of larvae and spat.....	369
6.2.3 Variations in gametogenic cycles	370
6.2.3.1 Intra-specific variations	370
6.2.3.2 Inter-specific variations	375
6.3 Regulation of gametogenic cycles	375
6.3.1 Gametogenesis and fecundity	376
6.3.1.1 Exogenous regulation	376
6.3.1.2 Endogenous regulation	381
6.3.2 Spawning and spawning synchrony	385
6.3.2.1 Exogenous regulation	385
6.3.2.2 Endogenous regulation	389
6.4 Energy metabolism	390
6.4.1 Tissue weights and indices.....	391
6.4.2 Tissue biochemical composition.....	392
6.4.3 Physiological indices	395
6.4.4 Radiotracer experiments	398
6.4.5 Ultrastructure and histochemistry	398
6.4.6 Mechanisms	400
6.5 Applications to aquaculture	401
6.5.1 Broodstock conditioning.....	401
6.5.2 Spawning	403
6.5.3 Larval growth and survival	403
6.6 Summary.....	404
6.6.1 Gametogenic cycles	404
6.6.2 Regulation of gametogenesis	404
6.6.3 Energy metabolism	405
6.6.4 Applications to aquaculture	406
References.....	406

Chapter 7. Physiology: Energy Acquisition and Utilisation

Bruce A. MacDonald, V. Monica Bricelj and Sandra E. Shumway

7.1 Introduction.....	417
7.2 Energy acquisition	417
7.2.1 Food sources	417
7.2.2 Feeding currents and mechanisms of particle capture	420
7.2.3 Particle retention efficiency	421
7.2.4 Feeding rates	424
7.2.5 Clearance rate in relation to food concentration	427
7.2.6 Influence of temperature on feeding rates.....	430

7.2.7 Pseudofeces production, pre- and post-ingestive particle selection	432
7.2.8 Absorption efficiency	436
7.2.9 Effects of suspended sediments on feeding and growth	439
7.2.10 Effects of flow on feeding and growth.....	445
7.2.11 Effects of harmful and toxic algae	447
7.3 Energy utilisation: Metabolic expenditure	453
7.3.1 Metabolic rate and oxygen availability	455
7.3.2 Metabolic cost of reproduction	458
7.3.3 Metabolic rate in relation to temperature and latitude	460
7.3.4 Metabolic rate in relation to activity levels.....	461
7.3.5 Anaerobic metabolism	463
7.4 Energy utilisation	467
7.4.1 Excretion and byssus secretion	467
7.4.2 Growth	468
References.....	474

Chapter 8. Physiological Integrations and Energy Partitioning

Raymond J. Thompson and Bruce A. MacDonald

8.1 Introduction.....	493
8.2 Energy balance, physiological integrations and the partitioning of energy between growth and reproduction	493
8.2.1 Energy budgets	493
8.2.2 Scope for growth.....	494
8.2.3 Growth efficiency and turnover ratio.....	494
8.2.4 Growth of shell and somatic tissue	495
8.2.5 Reproductive effort.....	496
8.3 Changes related to age of individuals	498
8.3.1 Scope for growth.....	498
8.3.2 Growth efficiency and turnover ratio.....	498
8.3.3 Somatic growth and maximum size	499
8.3.4 Somatic production and reproductive output	500
8.3.5 Reproductive effort.....	502
8.4 Environmental influence on production.....	504
8.4.1 Scope for growth and growth efficiency	504
8.4.2 Growth of shell and somatic tissue	506
8.4.3 Reproductive effort.....	509
8.5 Reproductive value and cost	511
8.5.1 Residual reproductive value.....	511
8.5.2 Reproductive cost	512
8.6 Population production	514
Acknowledgments	516
References.....	516

Chapter 9. Nutrition in Pectinids

Ana Farias and Iker Uriarte

9.1 Introduction.....	521
9.2 Pectinid feeding	521
9.3 Nutritional requirements during reproductive conditioning.....	528
9.4 Nutritional requirements of the larvae	529
9.5 Post-metamorphic nutritional requirements	533
9.6 Summary	536
References.....	536

Chapter 10. Genetics

Andy Beaumont

10.1 Introduction.....	543
10.2 Chromosomal genetics and ploidy manipulation	544
10.2.1 Chromosome numbers and karyotypes	544
10.2.2 Ploidy manipulation.....	548
10.3 Genetic markers and population genetics.....	550
10.3.1 Genetic markers	550
10.3.1.1 Allozymes.....	551
10.3.1.2 DNA methods	551
10.3.1.3 DNA based markers.....	552
10.3.1.3.1 Restriction fragment length polymorphism (RFLP)	552
10.3.1.3.2 Random amplified polymorphic DNA (RAPDs).....	552
10.3.1.3.3 Microsatellites	553
10.3.1.3.4 Amplified fragment length polymorphism (AFLP).....	553
10.3.1.4 Mitochondrial DNA in scallops	554
10.3.1.5 Types of data produced by different markers	555
10.3.1.6 Analysis of data	555
10.3.2 Overall genetic variation.....	557
10.3.3 Genetic differentiation of populations	559
10.3.3.1 <i>Placopecten magellanicus</i>	559
10.3.3.2 <i>Patinopecten</i> (= <i>Mizuhopecten</i>) <i>yessoensis</i>	561
10.3.3.3 <i>Pecten maximus</i>	562
10.3.3.4 <i>Aequipecten opercularis</i>	563
10.3.3.5 <i>Chlamys islandica</i>	564
10.3.3.6 <i>Chlamys farreri</i>	565
10.3.3.7 <i>Mimachlamys varia</i>	565
10.3.3.8 <i>Euvola</i> (<i>Pecten</i>) <i>ziczac</i>	565
10.3.3.9 <i>Argopecten gibbus</i>	565
10.3.3.10 The <i>Argopecten irradians</i> species complex.....	566
10.3.4 Genetic differences at species level and above	567
10.3.5 Heterozygote deficiency	568

10.3.6 Heterozygosity and growth	571
10.4 Quantitative genetics	575
10.4.1 Heritability and artificial selection	575
10.4.2 Inbreeding and hybridisation	577
10.5 Genome mapping and gene sequences	579
10.6 Conclusion	580
Acknowledgments	581
References	581

Chapter 11. Diseases and Parasites of Scallops

Sharon E. McGladdery, Susan M. Bower and Rodman G. Getchell

11.1 Introduction	595
11.2 Microbial diseases	595
11.2.1 Viruses	595
11.2.2 Prokaryota	605
11.2.2.1 Vibrionaceae	605
11.2.2.2 Intracellular prokaryotes (Rickettsiales; Chlamydiales and Mycoplasma)	607
11.2.2.3 Other bacterial pathogens of scallops	610
11.2.2.4 Bacterial management under hatchery conditions	611
11.3 Mycota	612
11.4 Protista	614
11.4.1 Sarcomastigophorea (Amoebae and Flagellates)	614
11.4.2 Labyrinthomorpha (Thraustochytrids and Labythinuloids)	615
11.4.3 Apicomplexa	615
11.4.3.1 Perkinsorida	615
11.4.3.2 Eucoccidiia	617
11.4.3.3 Eugregarinida	618
11.4.4 Microspora	619
11.4.5 Ascetospora	620
11.4.5.1 Marteiliida	621
11.4.5.2 Balanosporida	621
11.4.6 Ciliates	621
11.5 Platyhelminths	623
11.5.1 Trematodes	623
11.5.2 Cestodes	626
11.5.3 Turbellaria	626
11.5.4 Nematodes	628
11.6 Polychaetes	629
11.7 Crustacea	632
11.7.1 Pinnotheriidae	632
11.7.2 Copepodidae	632
11.8 Gastropods	633

11.9 Algae.....	635
11.10 Foraminiferans.....	636
11.11 Porifera.....	636
11.12 Cnidaria.....	637
11.13 Non-Infectious diseases.....	638
11.14 Summary.....	638
Acknowledgments.....	639
References.....	639

Chapter 12. Scallop Ecology: Distributions and Behaviour

Andrew R. Brand

12.1 Introduction.....	651
12.2 Geographical distribution.....	653
12.2.1 Geographical distribution of commercially important species.....	653
12.2.1.1 North Atlantic species.....	653
12.2.1.1.1 <i>Pecten maximus</i> and <i>P. jacobaeus</i>	653
12.2.1.1.2 <i>Aequipecten opercularis</i>	655
12.2.1.1.3 <i>Mimachlamys varia</i>	655
12.2.1.1.4 <i>Placopecten magellanicus</i>	655
12.2.1.1.5 <i>Argopecten irradians</i>	657
12.2.1.1.6 <i>Argopecten gibbus</i>	659
12.2.1.2 Sub-arctic species.....	659
12.2.1.2.1 <i>Chlamys islandica</i>	659
12.2.1.3 North Pacific species.....	661
12.2.1.3.1 <i>Patinopecten caurinus</i>	661
12.2.1.3.2 <i>Mizuhopecten yessoensis</i>	661
12.2.1.3.3 <i>Pecten albicans</i> , <i>Mimachlamys nobilis</i> and <i>Chlamys farreri</i>	662
12.2.1.4 Southern hemisphere species.....	662
12.2.1.4.1 <i>Pecten fumatus</i>	662
12.2.1.4.2 <i>Mimachlamys asperima</i> and <i>Equichlamys bifrons</i>	663
12.2.1.4.3 <i>Amusium balloti</i> and <i>A. pleuronectes</i>	664
12.2.1.4.4 <i>Pecten novaezelandiae</i>	664
12.2.1.4.5 <i>Argopecten purpuratus</i> and <i>A. ventricosus</i>	665
12.2.1.4.6 <i>Aequipecten tehuelchus</i>	665
12.2.1.4.7 <i>Zygochlamys patagonica</i>	665
12.2.2 Factors affecting geographical distribution.....	666
12.3 Local distribution.....	669
12.3.1 Spatial distribution.....	669
12.3.2 Year-class separation.....	676
12.3.3 Factors affecting local distribution.....	677
12.3.3.1 Depth.....	678
12.3.3.2 Substrate type.....	678

12.3.3.3 Currents	679
12.3.3.4 Turbidity	680
12.3.3.5 Salinity	681
12.3.3.6 Competitors and predators	684
12.4 Scallop behaviour - aspects affecting distribution	689
12.4.1 Byssus attachment	689
12.4.2 Recessing	692
12.4.3 Orientation	695
12.4.4 Swimming	698
12.4.5 Reactions to predators	707
12.4.6 Dispersal and migrations	709
12.5 Further study	712
Acknowledgments	713
References	713

Chapter 13. Scallops and Marine Contaminants

Peter J. Cranford

13.1 Introduction	745
13.2 Trace metals	746
13.3 Trace organics	748
13.4 Offshore oil and gas operations	750
13.5 Scallops as sentinel organisms	754
Acknowledgments	759
References	759

Chapter 14. Dynamics, Assessment and Management of Exploited Natural Populations

J.M. (Lobo) Orensanz, Ana M. Parma, Teresa Turk and Juan Valero

14.1 Introduction	765
14.2 Spatial scales	765
14.3 Population structure and dynamics	769
14.3.1 Aggregate stocks	769
14.3.1.1 Patterns of fluctuation	769
14.3.1.2 Climatic forcing	771
14.3.1.3 Correlation between consecutive life-history stages	773
14.3.1.4 The relation between aggregate stock and settlement/ recruitment	774
14.3.2 Macroscale	777
14.3.2.1 Patterns of connectivity: metapopulation structure	777
14.3.2.2 Metapopulation structure and geographic genetic differentiation	780

14.3.2.3 Larval retention/dispersal: mechanisms and oceanographic scenarios	782
14.3.2.4 Metapopulation models	784
14.3.3 Mesoscale	785
14.3.3.1 Persistence, extinction and resurgence of subpopulations	785
14.3.3.2 Relation between abundance and area occupied by a subpopulation	785
14.3.4 Microscale.....	786
14.3.4.1 Density, neighbourhoods and concentration.....	786
14.3.4.2 Concentration profiles	788
14.3.4.3 Density- vs. concentration-dependence; compensation vs. depensation.....	789
14.4 The fishing process	795
14.4.1 Types of fishing gear used in scallop fisheries	796
14.4.2 Effort and fishing mortality	797
14.4.2.1 Effort data	797
14.4.2.2 Effort units	797
14.4.2.3 Components of fishing mortality under homogeneity assumptions	798
14.4.2.4 Relative fishing power and standardisation of effort.....	799
14.4.3 Spatial patterns of effort allocation.....	799
14.4.4 The depletion process	803
14.4.5 Vulnerability and selectivity	805
14.4.6 Gear performance	806
14.4.7 Incidental fishing mortality and sub-lethal damage	808
14.5 Assessment.....	811
14.5.1 Macroscale.....	811
14.5.2 Mesoscale	812
14.5.2.1 Estimation of aggregated abundance: methods based on sampling	812
14.5.2.2 Mapping.....	815
14.5.2.3 Methods based on modelling the depletion process.....	816
14.5.3 Microscale.....	819
14.5.3.1 Small-scale spatial data.....	819
14.5.3.2 Spatial pattern	820
14.5.3.3 Scaling problems	821
14.6 Management.....	823
14.6.1 Types of scallop fisheries.....	823
14.6.2 Overfishing	824
14.6.2.1 Growth overfishing: yield-per-recruit (Y/R) analysis.....	824
14.6.2.2 Recruitment overfishing	826
14.6.2.3 A special case: recruitment fisheries.....	829
14.6.3 Sustainability	830

14.6.3.1 The precautionary approach to fisheries management (PAFM) and risk assessment (RA)	830
14.6.3.2 Marine protected areas (MPAs)	832
14.6.3.3 Ecosystem management concerns	834
14.6.3.4 Strategic structures: use and property rights	835
14.6.3.5 Diversification of the resource-base	837
14.6.4 Tactics	838
14.6.4.1 Size limits	838
14.6.4.2 Quota regulations	840
14.6.4.3 Escapement regulations	840
14.6.4.4 Direct effort regulations	840
14.6.4.5 Rotation	841
14.6.4.6 Direct interventions to enhance productivity	842
14.6.4.7 Experimental management	844
Acknowledgments	844
References	844
Endnotes	867

Chapter 15. Fisheries Sea Scallop, *Placopecten magellanicus*

K.S. Naidu and G. Robert

15.1 Introduction	869
15.2 Distribution	871
15.3 History of fishery	874
15.4 Population biology	878
15.5 Growth and yield per recruit	880
15.6 Gear and boats	883
15.7 Exploitation and resource management	886
15.8 Outlook	895
References	897

Chapter 16. Sea Scallop Aquaculture in the Northwest Atlantic

G. Jay Parsons and Shawn M. C. Robinson

16.1 Introduction	907
16.2 History of sea scallop culture	908
16.3 Hatchery spat production	909
16.3.1 Broodstock conditioning	909
16.3.2 Spawning methods	910
16.3.3 Egg and larval development	910
16.3.4 Settlement and metamorphosis	911
16.3.5 Spat husbandry	911
16.4 Wild spat collection	912
16.4.1 Spat collection techniques	912

16.4.2 Settlement intensity.....	913
16.4.3 Maximising spat collection.....	914
16.4.4 Spat growth.....	916
16.4.5 Spat sorting.....	916
16.5 Intermediate culture.....	916
16.5.1 Growth.....	917
16.5.2 Stocking density.....	917
16.5.3 Depth.....	919
16.5.4 Season.....	919
16.5.5 Location.....	919
16.5.6 Survival.....	920
16.5.7 Gear selection.....	920
16.5.8 Strategies for intermediate culture.....	921
16.6 Final grow-out.....	922
16.6.1 Suspension culture.....	922
16.6.2 Bottom culture.....	922
16.6.3 Growth.....	923
16.7 Scheduling and strategies.....	924
16.8 Site selection.....	924
16.8.1 Environmental criteria.....	925
16.8.1.1 Temperature and salinity regime.....	925
16.8.1.2 Ice coverage.....	925
16.8.1.3 Wind.....	925
16.8.1.4 Bottom type.....	925
16.8.1.5 Turbidity.....	926
16.8.2 Biological constraints.....	926
16.8.2.1 Predators.....	926
16.8.2.2 Fouling organisms.....	926
16.8.2.3 Phycotoxins.....	926
16.8.2.4 Diseases and parasites.....	927
16.9 Products and marketing.....	928
16.10 Economics.....	928
16.11 Social issues.....	929
16.12 Future prospects.....	930
Acknowledgments.....	930
References.....	930

Chapter 17. Bay Scallop and Calico Scallop Fisheries, Culture and Enhancement in Eastern North America

Norman J. Blake and Sandra E. Shumway

17.1 Introduction.....	945
17.2 Fisheries.....	945
17.2.1 Bay scallop, <i>Argopecten irradians</i>	945

17.2.1.1 Distribution	945
17.2.1.2 Biology	948
17.2.1.3 Fishery	950
17.2.2 Calico scallop, <i>Argopecten gibbus</i>	952
17.2.2.1 Distribution	952
17.2.2.2 Biology	953
17.2.2.3 Fishery	955
17.3 Aquaculture and enhancement	958
17.4 Future	961
References	961

Chapter 18. Scallops of the West Coast of North America

Raymond B. Lauzier and Neil F. Bourne

18.1 Introduction	965
18.2 Fisheries	967
18.2.1 Weathervane scallop	967
18.2.1.1 Biology	967
18.2.1.2 Fishery	971
18.2.1.3 Gear	973
18.2.1.4 Management	973
18.2.2 Rock scallop	973
18.2.2.1 Biology	974
18.2.2.2 Fishery	975
18.2.3 Pink and spiny scallops	975
18.2.3.1 Biology	975
18.2.3.2 Fisheries	977
18.2.3.3 Management	979
18.3 Aquaculture	979
18.3.1 Pink and spiny scallops	980
18.3.2 Weathervane scallop	980
18.3.3 Rock scallops	981
18.3.4 Japanese weathervane scallop	982
18.3.5 Pacific calico scallop	983
18.4 Future	983
Acknowledgments	984
References	984

Chapter 19. The European Scallop Fisheries for *Pecten maximus*, *Aequipecten opercularis* and *Mimachlamys varia*

Andrew R. Brand

19.1 Introduction	991
19.2 Biology and ecology	993

19.2.1 The great scallop, <i>Pecten maximus</i> (L.)	993
19.2.2 The queen scallop, <i>Aequipecten opercularis</i> (L.)	1006
19.2.3 The black or variegated scallop, <i>Mimachlamys varia</i> (L.)	1011
19.3 Fisheries	1014
19.3.1 Isle of Man	1017
19.3.2 Scotland	1023
19.3.3 England and Wales	1025
19.3.4 Northern Ireland	1027
19.3.5 Republic of Ireland	1027

Chapter 20. European Aquaculture

Mark Norman, Guillermo Román and Øivind Strand

20.1 Introduction	1059
20.2 <i>Pecten maximus</i>	1060
20.3 <i>Aequipecten opercularis</i>	1062
20.4 <i>Chlamys varia</i>	1063
20.5 Summary	1063
References	1063

Chapter 21. Scandinavia

Øivind Strand and G. Jay Parsons

21.1 Introduction	1067
21.2 <i>Chlamys islandica</i>	1067
21.2.1 Biology	1067
21.2.2 Fishery	1073
21.2.3 Aquaculture	1076
21.3 <i>Pecten maximus</i>	1077
21.3.1 Biology	1077
21.3.2 Fishery	1078
21.3.3 Aquaculture	1079
21.4 <i>Aequipecten opercularis</i>	1085
Acknowledgments	1086
References	1086

Chapter 22. Japan

Yoshinobu Kosaka and Hiroshi Ito

22.1 Introduction.....	1093
22.2 <i>Patinopecten (Mizuhopecten) yessoensis</i>	1099
22.2.1 Biology	1099
22.2.2 Fishery	1104
22.2.3 Culture	1111
22.2.4 Seed production	1111
22.2.5 Spat collection	1111
22.2.6 Intermediate culture.....	1116
22.2.7 Hanging culture.....	1116
22.2.8 Fouling.....	1118
22.2.9 Sowing culture	1120
22.2.10 Enemy clearance	1120
22.2.11 Seed sowing	1120
22.2.12 Care.....	1121
22.2.13 Recapture	1121
22.2.14 Value.....	1124
22.2.15 Processing	1127
22.2.16 Occurrence of shellfish poisoning.....	1130
22.3 Future	1130
22.3.1 Technology	1130
22.3.2 Control of culture.....	1133
22.3.3 Cost-reduction.....	1133
22.3.4 Concept.....	1133
22.4 <i>Pecten albicans</i>	1134
22.4.1 Biology	1134
22.4.2 Fishery	1134
22.4.3 Culture	1135
22.5 <i>Chlamys (Mimachlamys) nobilis</i>	1135
22.5.1 Biology	1135
22.5.2 Culture	1135
Acknowledgments	1136
References.....	1136

Chapter 23. Scallop Culture in China

Ximing Guo and Yousheng Luo

23.1 Introduction.....	1143
23.2 Zhikong scallop.....	1146
23.2.1 Shell morphology.....	1146
23.2.2 Distribution	1146
23.2.3 Growth	1147

23.2.4 Reproduction.....	1149
23.3 Other scallop species.....	1151
23.3.1 Huagui scallop	1151
23.3.2 Non-native species.....	1152
23.4 Fishery	1153
23.5 Aquaculture.....	1154
23.5.1 Species and history	1154
23.5.2 Collection of natural seed for Zhikong scallop.....	1155
23.5.3 Hatchery production of bay scallop	1155
23.5.4 Grow-out.....	1158
23.6 Harvest, processing and marketing	1160
Acknowledgments	1160
References.....	1161

Chapter 24. Scallops Fisheries and Aquaculture of Northwestern Pacific, Russian Federation

Victor V. Ivin, Vasily Z. Kalashnikov, Sergey I. Maslennikov and Vitaly G. Tarasov

24.1 Introduction.....	1163
24.2 Taxonomic status	1163
24.3 Biology and ecology	1164
24.3.1 <i>Chlamys albida</i>	1164
24.3.2 <i>Chlamys asiatica</i>	1166
24.3.3 <i>Chlamys behringiana</i>	1167
24.3.4 <i>Chlamys chosonica</i>	1168
24.3.5 <i>Chlamys farreri</i>	1170
24.3.6 <i>Chlamys swifti</i>	1172
24.3.7 <i>Delectopecten randolphi</i>	1174
24.3.8 <i>Mizuhopecten yessoensis</i>	1174
24.3.8.1 Total populations and biomass	1175
24.3.8.2 Distribution in Primorye	1176
24.3.8.3 Distribution over depths	1176
24.3.8.4 Age structure of scallop settlements	1176
24.3.8.5 Scallop growth.....	1177
24.3.8.6 Sex structure of settlements	1178
24.3.8.7 Replenishment	1181
24.3.8.8 Spawning	1181
24.3.8.9 Larvae morphology.....	1182
24.3.8.10 Development in plankton.....	1182
24.3.8.11 Migration behaviour	1184
24.3.8.12 Risk factors	1184
24.3.8.12.1 Abiotic factors	1184
24.3.8.12.2 Storms.....	1184
24.3.8.12.3 Predators.....	1185

24.3.8.12.4 Parasites.....	1187
24.3.8.12.5 Bacterial contamination.....	1189
24.3.8.12.6 Epibionts.....	1189
24.4 Fishing and aquaculture.....	1189
24.4.1 Fishing.....	1189
24.4.1.1 History.....	1189
24.4.1.2 Fishing gear.....	1191
24.4.1.3 Yesso scallop landings.....	1191
24.4.1.3.1 Primorsky territory.....	1191
24.4.1.3.2 Sakhalin-Kurile region.....	1192
24.4.1.4 Yesso scallop commercial stock.....	1192
24.4.1.4.1 Primorsky territory.....	1192
24.4.1.4.2 Sakhalin-Kurile region.....	1192
24.4.1.4.2.1 Aniva Bay.....	1194
24.4.1.4.2.2 Terpenie Bay.....	1194
24.4.1.4.2.3 Kuriles.....	1194
24.4.1.5 Commercial <i>Chlamys</i> scallops.....	1194
24.4.1.5.1 Primorye.....	1194
24.4.1.5.2 Kurile Islands.....	1195
24.4.1.5.3 In Bering Sea.....	1196
24.4.1.6 Other <i>Chlamys</i> species.....	1196
24.4.1.6.1 <i>Chlamys farreri</i>	1196
24.4.1.6.2 <i>Chlamys swifti</i>	1196
24.4.2 Aquaculture.....	1196
24.4.2.1 History.....	1196
24.4.2.2 Present situation.....	1197
24.4.2.3 Marketing.....	1198
24.4.2.4 The culture methods.....	1198
24.4.2.4.1 Spat collection.....	1198
24.4.2.4.2 Intermediate culture.....	1199
24.4.2.4.3 Transport of scallop seed.....	1199
24.4.2.4.4 Sowing or on-bottom culture.....	1200
24.4.2.4.5 Hanging or off-bottom culture.....	1201
24.4.2.4.6 Obstacles to mariculture development.....	1201
24.4.2.4.7 Ecological constraints associated with cultivation.....	1202
24.4.2.4.7.1 Predation.....	1202
24.4.2.4.7.2 Epibionts.....	1202
24.4.2.4.7.3 Biofouling of cultivation structures.....	1203
24.4.2.4.8 Effect of scallop mariculture on coastal ecosystems....	1204
24.4.2.5 Future prospects.....	1211
Acknowledgments.....	1213
References.....	1213

Chapter 25. Scallop Aquaculture and Fisheries in Brazil

Guilherme S. Rupp and G. Jay Parsons

25.1 Introduction.....	1225
25.2 <i>Nodipecten nodosus</i> – biology, aquaculture and fisheries.....	1227
25.2.1 Taxonomy and distribution.....	1227
25.2.2 Ecology.....	1228
25.2.3 Reproduction.....	1231
25.2.4 Aquaculture.....	1232
25.2.4.1 Status.....	1232
25.2.4.2 Culture technology.....	1233
25.2.4.2.1 Wild seed collection.....	1233
25.2.4.2.2 Hatchery production.....	1234
25.2.4.2.3 Growout.....	1236
25.2.4.2.4 Constraints.....	1239
25.2.5 Fisheries and marketing.....	1239
25.2.6 Future prospects.....	1240
25.3 <i>Euvola (Pecten) ziczac</i> – biology, aquaculture and fisheries.....	1240
25.3.1 Taxonomy and distribution.....	1240
25.3.2 Ecology.....	1241
25.3.3 Reproduction.....	1241
25.3.4 Aquaculture.....	1242
25.3.4.1 Status.....	1242
25.3.4.2. Culture technology.....	1242
25.3.4.2.1 Wild seed collection.....	1242
25.3.4.2.2 Hatchery production.....	1242
25.3.4.2.3 Growout.....	1243
25.3.4.2.4 Constraints.....	1243
25.3.5 Fisheries.....	1243
25.3.6 Future prospects.....	1244
Acknowledgments.....	1244
References.....	1245

Chapter 26. ArgentinaNéstor F. Ciocco, Mario L. Lasta, Maite Narvarte, Claudia Bremec, Eugenia Bogazzi,
Juan Valero and J.M. (Lobo) Orensanz

26.1 Introduction.....	1251
26.2 The Tehuelche scallop, <i>Aequipecten tehuelchus</i>	1251
26.2.1 Biology.....	1251
26.2.2 Population dynamics.....	1257
26.2.3 Fisheries.....	1258
26.2.3.1 The inshore dredge fishery of San Matías Gulf.....	1258
26.2.3.2 The commercial diving fishery of San José Gulf.....	1261

26.2.4 Aquaculture.....	1263
26.2.4.1 Spat collection	1263
26.2.4.1.1 Vertical distribution of settlement	1263
26.2.4.1.2 Temporal variation in settlement	1263
26.2.4.1.3 Type of collector.....	1263
26.2.4.1.4 Location.....	1265
26.2.4.1.5 Influence of depth, type of collector and location on the average size of the 'seed'	1265
26.2.4.2 Growth in suspended structures of spat obtained from collectors	1266
26.2.4.3 Larval culture in the laboratory	1268
26.2.4.4 Prospects and problems	1268
26.3 The Patagonian scallop, <i>Zygochlamys patagonica</i>	1269
26.3.1 Biology and ecology	1269
26.3.2 Population dynamics and stock assessment	1273
26.3.3 The fishery	1275
26.3.3.1 Exploratory surveys and experimental fishing programs.....	1275
26.3.3.2 Management	1276
26.3.3.3 Development of the fishery.....	1277
26.3.3.4 Observers program.....	1280
26.3.3.5 Ecological effects of fishing	1281
26.3.3.6 Marketing.....	1283
Acknowledgments	1283
References.....	1283

Chapter 27. Scallop Fishery and Aquaculture in Chile

Elisabeth von Brand, German E. Merino, Alejandro Abarca and Wolfgang Stotz

27.1 Introduction.....	1293
27.2 Species description.....	1293
27.2.1 <i>Argopecten purpuratus</i> (Lamarck 1819) the northern scallop	1295
27.2.2 <i>Zygochlamys patagonica</i> (King and Broderip 1831) the southern scallop	1295
27.2.3 <i>Chlamys vitrea</i> (King & Broderip, 1831) the southern scallop.....	1296
27.3 Fisheries	1296
27.3.1 <i>Argopecten purpuratus</i> , the northern scallop.....	1296
27.3.2 <i>Chlamys vitrea</i> and <i>Zygochlamys patagonica</i> , the southern scallop.....	1298
27.4 How scallop aquaculture started in Chile.....	1299
27.5 Aquaculture production.....	1301
27.5.1 Production stages	1303
27.5.1.1 Hatchery broodstock conditioning and spawning.....	1303
27.5.1.2 Larval stage.....	1303
27.5.1.3 Settlement, metamorphosis and postlarval stage	1304

27.5.1.4 Seed supply	1305
27.5.1.5 Ongrowing stage	1305
27.5.2 Constraints and opportunities for northern scallop hatcheries	1306
27.5.3 Interaction between natural beds and aquaculture	1307
27.5.4 Recovery of a natural bed of <i>Argopecten purpuratus</i>	1308
27.5.5 Final overview and projections of Chilean scallop farming	1308
Acknowledgments	1311
References	1311

Chapter 28. Venezuela

César J. Lodeiros, Luis Freitas, Maximiano Nufiez, Anibal Vélez and John H. Himmelman

28.1 Introduction	1315
28.2 Distribution, habitat and reproduction	1315
28.2.1 <i>Euvola (Pecten) ziczac</i>	1315
28.2.2 <i>Argopecten nucleus</i>	1319
28.2.3 <i>Nodipecten (Lyropecten) nodosus</i>	1319
28.2.4 <i>Amusium papyraceum</i> and <i>Amusium laurenti</i>	1320
28.3 Fisheries	1320
28.4 Aquaculture	1322
28.4.1 <i>Euvola ziczac</i>	1322
28.4.1.1 Gonad maturation and spawning	1322
28.4.1.2 Spat production	1322
28.4.1.3 Grow-out	1323
28.4.2 <i>Nodipecten nodosus</i>	1326
28.4.2.1 Gonad maturation and spawning	1326
28.4.2.2 Spat production	1326
28.4.2.3 Grow-out	1326
28.4.3 <i>Argopecten nucleus</i>	1329
28.5 Perspectives for culture	1330
References	1332

Chapter 29. Mexico

Esteban Fernando Félix-Pico

29.1 Fishery	1337
29.1.1 Introduction	1337
29.1.2 Species and distribution of scallops	1338
29.1.3 History of the fishery	1339
29.1.4 Status of the resource	1340
29.1.4.1 Reproductive biology	1340
29.1.4.1.1 Size at maturity	1340
29.1.4.1.2 Fecundity	1341

29.1.4.1.3 Maturity and spawning	1341
29.1.4.2 Population biology	1344
29.1.4.3 Abundance and density	1345
29.2 Exploitation of the resource	1347
29.2.1 Fishing areas	1347
29.2.2 Fishing seasons	1348
29.2.3 Fishing operations and results	1349
29.2.4 The market value-landings data from 1970 to 2000	1349
29.3 Constraints	1350
29.3.1 Pollution	1350
29.3.2 Biological constraints	1352
29.3.3 Predation	1353
29.3.4 Resource management constraints	1354
29.4 Harvesting and transporting	1354
29.4.1 Methods	1354
29.4.2 Marketing	1355
29.5 Expected future	1356
29.6 Aquaculture	1357
29.6.1 Introduction	1357
29.6.2 Species	1358
29.6.3 History	1358
29.7 Hatchery techniques	1359
29.7.1 Conditioning	1359
29.7.2 Induction of spawning and fertilisation	1360
29.7.3 Larval culture and metamorphosis	1361
29.7.4 Genetic enhancement	1366
29.7.4.1 Selection	1366
29.7.4.2 Crossbreeding	1366
29.7.4.3 Triploidy	1367
29.7.5 Antibiotics	1368
29.8 Natural spat	1368
29.8.1 Methods employed	1368
29.8.2 Spat collection	1369
29.9 Growth	1372
29.9.1 Suspended cultures	1372
29.9.2 Bottom cultures	1375
29.9.3 Factors influencing growth	1376
29.10 Mortality	1377
29.10.1 Suspended culture	1377
29.10.2 Bottom culture	1378
29.11 Constraints	1379
29.12 Future prospects	1379

Chapter 1

New Phylogenies of the Pectinidae (Mollusca: Bivalvia): Reconciling Morphological and Molecular Approaches

Thomas R. Waller

1.1 INTRODUCTION

Waller (1991) postulated evolutionary relationships among commercial scallops on the basis of shared derived morphological characters and produced a phylogeny scaled against geologic time using data from the fossil record. In the past decade, molecular genetic studies have tested most of the branching points in the original phylogeny. Although the morphological and molecular genetic trees have been largely concordant, there are some differences and some new findings that merit further testing and discussion. In the present study, I review the phylogenetic results of the molecular genetic studies and then present new data and new phylogenetic interpretations from an extensive study of the worldwide fossil record of the Pectinidae beginning at the dawn of the Cenozoic Era. The new phylogenies resolve at least some of the conflicts between morphological and molecular approaches. They also provide new hypotheses for further testing by both approaches.

1.1.1 Molecular Genetic Studies

Rice et al. (1993) analysed full sequences of the 18S rRNA gene from the pectinid species *Placopecten magellanicus* (Gmelin, 1791), *Chlamys islandica* (Müller, 1776), and *Argopecten irradians* (Lamarck, 1819) and seven species in the heterodont family Mactridae, with a branchiuran crustacean serving as an outgroup to the Bivalvia. Pectinid monophyly was supported by 100% bootstrap values for all methods of analysis. Parsimony and maximum-likelihood analyses placed either *Chlamys* or *Placopecten* first depending upon which gap value was chosen for the analysis. In contrast, Fitch-Margoliash distance analyses placed *Placopecten* first regardless of the gap values. *Argopecten irradians* consistently appeared as the latest branch among the three species, with either *Placopecten magellanicus* or *Chlamys islandica* as its sister species. With reference to these three species, Waller (1991, fig. 8) showed *Placopecten* (as a member of the “*Palliothum* group”) branching off first and *Argopecten* (as a member of the “*Aequipekten* group”) last. Waller (1984) had earlier concluded that the Pectinidae are monophyletic based upon the presence in all members of the group of a ctenolium, shown to be an autapomorphy for the family Pectinidae.

Kenchington and Roddick (1994) corroborated pectinid monophyly through analyses of the 18S rRNA gene in an expanded group of taxa that included additional bivalves (*Crassostrea*, *Mytilus*) as well as representatives of other molluscan classes (a gastropod and a chiton) and a spider used as a distant outgroup. Again, their pectinid phylogeny showed monophyly of the family Pectinidae and either *Chlamys* or *Placopecten* branching first among the same three pectinid species analysed by Rice et al. (1993).

Steiner and Müller (1996) analysed complete and partial 18S rDNA sequences from the same bivalve taxa plus two additional bivalves (*Atrina*, *Arca*), an additional gastropod and chiton, and a polychaete annelid as a distant outgroup. All methods of tree construction showed the same three species of Pectinidae referred to above to be a monophyletic group. In contrast to the preceding studies, however, their use of spectral analysis (Hendy and Penny 1993) found *Argopecten* branching first with no conflict but with little support. Among the most parsimonious trees in parsimony analysis of the sequence data, they found that either *Placopecten* or *Argopecten* branched first depending on whether *Crassostrea* is the sister group of the Pectinidae. All of their other tree reconstructions, however, indicate *Argopecten* as the first pectinid branch, i.e., as the sister group of *Placopecten magellanicus* plus *Chlamys islandica*, in contrast to Waller's (1991) phylogeny.

Frischer et al. (1998) used 18S rRNA gene sequence data, including alignments based on secondary structural constraints, from seven pectinid species: the three species mentioned above plus *Pecten maximus* (Linnaeus, 1758), *Chlamys hastata* (G.B. Sowerby, II, 1842), *Mimachlamys varia* (Linnaeus, 1758), and *Crassadoma gigantea* (Gray, 1825). Again, monophyly of the Pectinidae was firmly supported by both distance and parsimony methods. However, their analyses also provided very strong support for a closer relationship of *Pecten maximus* and *Argopecten irradians* to each other than to the other pectinid species. This is in contrast to Waller (1991), who placed *Pecten* on the same side of a deep split in the Pectinidae as *Placopecten* (in the *Palliolum* group) and placed *Argopecten* (in the *Aequipekten* group) on the other side of this split with the *Chlamys* and *Mimachlamys* groups (see Fig. 1.1 herein). Frischer et al. (1998) also found that the tribes Chlamydini and Mimachlamydini "generally group together, sharing a common ancestor with the Crassadomini and Palliolini" but with bootstrap values ranging widely depending upon the methods used.

Hayami and Matsumoto (1998) tested the phylogenies of Waller (1991, 1993) by analysing the mitochondrial cytochrome oxidase subunit I (COI) gene of seven Japanese scallop species: *Amusium japonicum* (Gmelin, 1791), *Cryptopecten vesiculosus* (Dunker, 1877), *Pecten albicans* (Schröter, 1802), *Mimachlamys nobilis* (Reeve, 1852), *Azumapecten farreri* (Jones and Preston, 1904), *Patinopecten yessoensis* (Jay, 1856), and *Swiftopecten swifti* (Bernardi, 1858). The oyster, *Crassostrea gigas* (Thunberg, 1793), was used as the outgroup. They found support for a clade containing *Amusium*, *Cryptopecten*, and *Pecten* forming a sister group of a clade containing *Mimachlamys*, *Azumapecten*, and *Patinopecten* + *Swiftopecten*, branching in that order. *Cryptopecten* is an aequipectinine genus closely related to *Argopecten*. Its sister-group relationship to *Pecten* shown by the COI gene analyses corroborates the close relationship of *Argopecten* and *Pecten* found by Frischer et al. (1998), in contrast to the well separated positions of

these genera in the 1991 phylogeny of Waller (Fig. 1.1). Their phylogeny of the other genera, however, is similar to the relationships within the Chlamydinae indicated in Waller (1991, 1993).

Figure 1.1. A phylogeny of groups of Pectinidae containing commercial species plotted against time reconstructed from Waller (1991, figs. 8 and 11 and text). Phyletic lines ending in arrows contain extant representatives, those ending in cross-bars are extinct. Double lines crossing a lineage indicate that its phylogenetic position has been changed in the present study. Dates of period or epoch boundaries, in millions of years, are from Berggren et al. (1995) for the Cenozoic Era and from Harland et al. (1990) for the Mesozoic Era.

Giribet and Carranza (1999) and Steiner (1999) found full support for monophyly of the Pectinidae in analyses of 18S rDNA sequences for the same seven pectinid species that were considered by Frischer et al. (1998). Giribet and Carranza's (1999: figs. 1a-c) most parsimonious trees using the complete alignment and unweighted parsimony gave identical arrangements of *Placopecten*, *Chlamys*, and *Argopecten* whether obtained by branch-and-bound search or by heuristic search. In both cases *Argopecten* is a sister group of *Chlamys* + *Placopecten*. Their strict consensus tree of 18 most parsimonious trees using heuristic search shows three sister groups: (a) *Argopecten* + *Pecten*, (b) species in the genera *Chlamys*, *Mimachlamys*, and *Crassadoma*, and (c) *Placopecten*. Steiner (1999) reanalysed the same data set and showed similar phylogenetic results for the Pectinidae.

Canapa et al. (1999, 2000a) determined a complete sequence of 18S ribosomal DNA for *Adamussium colbecki* (Smith, 1902), a large, smooth, thin-shelled scallop that is abundant around Antarctica. In analyses using sequences from the seven pectinid species mentioned above plus *Adamussium*, both neighbour-joining and maximum-parsimony methods yielded trees similar to those of Frischer et al. (1998). Here again, a close relationship between *Pecten maximus* and *Argopecten irradians* is supported by a high bootstrap value. *Adamussium* is shown as a sister group of this pair of taxa, but with a low bootstrap value. *Chlamys islandica*, *Chlamys hastata*, and *Mimachlamys varia* also form a clade with high bootstrap value. *Crassadoma gigantea* is close to these, but the position of *Placopecten* is uncertain. As the authors point out (p. 381), *Placopecten* appears close to *Chlamys* where the analysis includes other pteriomorphian families but "appears equidistant from *Chlamys* and the *Pecten-Aequipekten* groups when only pectinid sequences are considered."

Wilding et al. (1999) examined the genetic relationships of two European species, *Pecten maximus* and *P. jacobaeus* (Linnaeus, 1758), that have long been regarded as closely related but distinct species by malacologists and palaeontologists. Using allozyme electrophoresis and a type of mitochondrial DNA analysis (DNA PCR-RFLP) previously applied to populations, they found that genetic distances were of a magnitude "considerably lower than expected for congeneric species." However, rather than accepting the low genetic distances as evidence for conspecificity, the authors carefully reviewed the conflicting lines of evidence and suggested three possibilities for explaining the conflict: (a) The two are indeed valid species but this is not reflected in the particular genetic indices calculated. (b) These are not distinct species, meaning that both would carry the name *Pecten maximus*, the prior name in Linnaeus (1758). In this case the morphological differences would be ecophenotypic, i.e., reflecting local environmental conditions, and the allozyme differentiation "merely represents increased isolation by distance" between the two samples (*P. maximus* sampled from Britain, Ireland, and northern France, *P. jacobaeus* from southeastern Spain). This would require demonstration of range overlap and evidence of hybridisation in nature. Thus far, however, the authors point out that hybridisation to produce viable adults has been demonstrated only under laboratory conditions. The matter of range overlap is discussed further in the following section on new observations. (c) *P. jacobaeus* from southeastern Spain are interbreeding with *P. maximus* but interbreeding may not occur elsewhere, thus

leading to an anomalously low genetic distance between the species. The authors discounted this possibility, however, in noting that there is an oceanographic front stretching across the Mediterranean from Almería, Spain, to Oran, Algeria, that has been associated with genetic breaks in the distributions of other marine species. Logically this front could separate *P. maximus*, a species of the northeastern Atlantic, from *P. jacobaeus*, a Mediterranean species. In this case, however, the population of *P. jacobaeus* sampled came from the Mediterranean side of the front, where interbreeding would not be expected. Wilding et al. (1999) concluded, after considering these possibilities, that the conflict between genetic-distance data that indicate conspecificity and morphological, biogeographical, and paleontological data that indicate species distinctness is still unresolved.

Canapa et al. (2000b, fig. 1) used partial sequences of the 16S rRNA gene to analyse the phylogenetic relationships of seven scallop species which they referred to as *Adamussium colbecki*, *Aequipecten opercularis* (Linnaeus, 1758), *Chlamys glabra* (Linnaeus, 1758), *Chlamys varia*, *Pecten jacobaeus*, and *Pecten maximus*. As indicated above, their two “*Chlamys*” species have been assigned to other genera and now bear the names *Mimachlamys varia* and *Flexopecten glaber* (see Waller 1986, 1991, 1993). The inclusion of a species of *Flexopecten* is of interest, because according to Waller (1991, but see below) it represents the “*Decatopecten* group”, no representative of which had been previously analysed using molecular genetic information. The trees illustrated by Canapa et al. (2000b, figs. 1 and 2) are topologically identical to each other. With a *Mytilus* as the outgroup, these indicate the monophyly of the Pectinidae. Within the Pectinidae, they show *Aequipecten opercularis* and *Flexopecten glaber* as a sister group of the other five pectinid taxa. This is in contrast to Waller (1991), where *Flexopecten*, as a member of the *Decatopecten* group, is distant from *Aequipecten*. Within the five species that Canapa et al. (2000b) analysed, two European species of *Pecten* are joined by bootstrap values of 100%. Lower bootstrap values (93% and 95%) join *Adamussium colbecki* with *Chlamys islandica* and *Mimachlamys varia*. Their analysis, like that of Wilding et al. (1999), demonstrated a relationship between *Pecten maximus* and *P. jacobaeus* that is so close that it would appear to challenge the existing taxonomic concept that these taxa are distinct species. Although Canapa et al. (2000b) contend that this proximity is corroborated by evidence of morphological intergradation, the validity of this morphological evidence is questioned below.

Matsumoto and Hayami (2000) analysed sequences of the mitochondrial cytochrome c oxidase subunit I gene (COI) of 17 pectinid species, by far the most taxonomically extensive molecular genetic study of scallops performed thus far. The species are distributed among most of the clades discussed by Waller (1991), including the *Chlamys*, *Mimachlamys*, *Aequipecten*, *Decatopecten*, and *Pecten* groups. Groups not analysed are the *Palliolium* group and the pectinid genus *Delectopecten*, the latter hypothesised by Waller to be the sister group of all other extant Pectinidae. The authors also analysed the COI gene in two additional families of the superfamily Pectinoidea, Propeamussiidae (one species) and Spondyliidae (four species) using a limid bivalve (*Limnaria*) and an arcoidean bivalve (*Scapharca*) as outgroups of the pectinoidean families.

The phylogenetic results of the COI analysis are remarkably concordant with the morphological phylogenies of Waller (1978, 1984, 1991, 1993). The Spondylidae and Propeamussiidae, as predicted, fall outside of the family Pectinidae. Within the Pectinidae, the subfamily Chlamydinae is a sister group of the family Pectininae. The former contains the tribes Chlamydini and Mimachlamydini, whereas the latter contains the Decatopectinini and Pectinini as sister groups. At a finer level within the Chlamydini, the bizarre, coral-inhabiting species *Pedum spondyloideum* Lamarck, 1819, is shown to be a sister group of *Laevichlamys squamosa* (Gmelin, 1791) + *Semipallium diana* (Crandall, 1979). Waller (1993) had predicted a close relationship between *Pedum* and his new genus *Laevichlamys* based upon the early development of shell morphology and microsculpture in the two groups. Waller's (1993: 27) placement of *Patinopecten* close to *Chlamys*, in contrast to its previous position close to *Pecten*, is also corroborated, as is also a close relationship between the Decatopectinini and Pectinini. Waller's separation of the Propeamussiidae from the Pectinidae (Waller 1972, 1978, 1984) and placement of true *Amusium* close to *Pecten* is also corroborated, although in the COI phylogeny, *Amusium* is more basal in the Pectininae, branching off before the split of the *Decatopecten* and *Pecten* groups (but with low bootstrap value).

There are also, however, some conflicts between the COI phylogeny and the previous morphological phylogenies. As in the other molecular genetic studies mentioned above, an aequipectinine genus, *Cryptopecten*, is shown to have a closer relationship to *Pecten* than to any other genus that they analysed. Also, there is also no clear indication in the COI analysis that the subfamily Pectininae is closer to the tribe Mimachlamydini than to other members of the Chlamydinae. Matsumoto and Hayami (2000) did not analyse the COI gene in any member of the *Palliolum* group of Waller and thus did not address the persistent problem of the relationship of *Placopecten* to other pectinids.

Steiner and Hammer (2000) examined phylogenetic relationships throughout the Pteriomorpha by aligning new, nearly complete 18S rDNA sequences with those previously published. For the Pectinidae, they included the seven species analysed by Frischer et al. (1998) but added sequences from three more species: *Flexopecten glaber* (Linnaeus, 1758), *Excellichlamys spectabilis* (Reeve, 1853), and *Pedum spondyloideum* (Gmelin, 1791). Parsimony and maximum-likelihood trees have *Crassadoma*, *Placopecten*, *Chlamys*, and *Pedum* at the base and a series represented successively by *Mimachlamys*, *Excellichlamys*, *Pecten*, and *Argopecten* + *Flexopecten* at higher levels. These results corroborate those of the earlier molecular genetic studies. The position of the newly analysed *Excellichlamys*, however, is of considerable interest, because it is well separated from *Flexopecten* and is located below the *Pecten*-*Argopecten*-*Flexopecten* clade. This is in contrast to Waller (1986, 1991), who included *Excellichlamys* with *Flexopecten* in the same tribe Decatopectinini.

Campbell (2000) used 18S gene sequences to examine phylogeny through the entire class Bivalvia. The relationships of four pectinid taxa (*Placopecten magellanicus*, *Chlamys islandica*, *Argopecten irradians*, and *Pecten maximus*) were similar to those of previous studies, with *Placopecten* branching off first, then *Chlamys*, and then *Pecten* + *Argopecten*.

The issue of whether western *Pecten jacobaeus* and *P. maximus* are distinct at the species level was re-examined by Ríos et al. (2002). Using allozyme electrophoresis, they analysed variation in 15 allozyme loci of *Pecten maximus* and *P. jacobaeus*, respectively, on the west and east sides of the Almería-Oran Oceanographic Front in the western Mediterranean. They found evidence for a major genetic discontinuity between these taxa where they are separated by the oceanographic front.

The principal uncertainties or conflicts in comparisons of the morphological and molecular phylogenies outlined above raise a number of questions: (a) Is *Placopecten* representative of a deep split in the Pectinidae? If so, when did this split occur, and what are the paleontological roots of *Placopecten*? (b) If *Pecten* and the aequipectinine genera *Argopecten* and *Cryptopecten* are as closely related as indicated by molecular genetic studies, can this be reconciled with the fossil record of the origins of these groups? (c) If *Flexopecten* is closely related to *Aequipecten* and *Argopecten* and is separated from *Excelllichlamys*, is it still a member of the *Decatopecten* group, or do morphology and the fossil record indicate that *Flexopecten* and the *Decatopecten* group have independent origins? (d) Molecular genetic studies indicate that two long-recognised species of the eastern Atlantic and Mediterranean, *Pecten maximus* and *P. jacobaeus*, respectively, are so genetically close that it is possible that they belong to the same species. A recent allozyme study, however, discovered a major genetic continuity between these species in the western Mediterranean. What more do morphology and the fossil record have to say about the distinction between these taxa?

1.1.2 Methods and Materials

Morphological terms used herein are explained in Waller (1991). Particularly important are the three terms describing the orientation of sculptural features: “antimarginal”, referring to sculptural features that trace sweeping lines that are approximately perpendicular to the margin; “radial”, referring to features that radiate from the beak and are therefore approximately perpendicular to the margin only in the central radial sector; and “commarginal” describing features that parallel the margin. Terms for hinge teeth with reference to the right valve were introduced in Waller (1986) and were further refined in Waller (1991: 8). Terms for adaptive shell shapes (chlamydoid, aequipectinoid, pectinoid, amusioid), discussed in Waller (1991: 10), refer to forms that have evolved over and over again in the history of the Pectinidae. These forms may be taxonomically important within clades defined on the basis of other characters but do not in themselves denote high-level taxa. Morphological clues to high-level pectinid relationships lie in the development of microsculpture, megasculpture, shell microstructure, and hinge dentition.

The phylogenies resulting from the present study (Figs. 1.2 and 1.3) are scaled against geologic time calibrated in millions of years and compartmentalised into standard European stages. For convenience, these European stage/age names have been used throughout the text rather than local names. The basis for calibration is the set of charts in Berggren et al. (1995) that relate global zones based on planktonic foraminifera, calcareous nannoplankton, magnetic polarity data, and radiometric data to European

Figure 1.2. A phylogeny of the six tribes of the subfamily Palliolinae. Dashed lines indicate missing fossil records. Letter-number labels of nodes refer to characters discussed in text. Numbers on stage boundaries refer to time in millions of years ago. Positions of origins of lineages within stages are not significant. Other conventions are as in Figure 1.1.

stages. In general, the process of placing an age on a local fossil occurrence has involved (a) determining the geological formation in which the fossil occurs, either from original collection data or later stratigraphic updates in the literature, (b) determining from the literature whether there is microfossil zonal information for that formation or for formations that are in stratigraphic proximity, and (c) using the microfossil zonal

determinations for entry into the Berggren et al. (1995) charts. Particularly useful sources of information on fossil occurrences and stratigraphic correlation via microfossil zones have been Palmer and Brann (1965), Ward and Blackwelder (1980), Blackwelder (1981), Siesser (1984), Ward (1985, 1992), Carter and Rossbach (1989), Harland et al. (1990), and Beu and Maxwell (1990).

Figure 1.3. A phylogeny of three tribes of the subfamily Pectininae. See Figures 1.1 and 1.2 for explanation of numbers and symbols.

Almost all of the taxa referred to in this study have been examined first-hand by means of dissecting microscopes. High-intensity oblique lighting and, in some cases, coating with ammonium chloride, have been useful for bringing out details of sculptural features of low relief. European fossil taxa have been studied at major natural history museums, particularly in London, Brussels, Paris, and Lyon. Fossil taxa from the Americas have been studied mainly at the National Museum of Natural History, Smithsonian Institution, Washington. Information on the morphology of extant species is mainly from the extensive collections of the Department of Systematic Biology (Mollusk Division) at the National Museum of Natural History, Smithsonian Institution.

1.2 NEW OBSERVATIONS

1.2.1 Subfamily Camptonectinae Habe, 1977

Waller (1991, fig. 8) and Waller and Marincovich (1992: 219) indicated that the extant cosmopolitan genus *Delectopecten* Stewart, 1930, is a descendant of the extinct Jurassic-Cretaceous genus *Camptonectes* Agassiz in Meek, 1864, which in turn is derived from *Pleuronectites* von Schlotheim, 1820, of the Triassic. By this phylogenetic scheme, *Delectopecten* is a sister taxon of all other extant Pectinidae, with the last common ancestor in the early Middle Triassic (early Anisian), approximately 240 million years ago. New research by the author on Middle Triassic pectinids has led to a new concept of *Pleuronectites* as an evolutionary dead-end that underwent its main evolutionary change within the Muschelkalk Basin of southwestern Europe. In the course of its evolution within this basin in the Triassic, the genus reached gigantic size and became more inequivalved, with the right valve nearly flat and the left valve becoming greatly inflated (Hagdorn 1995). All *Pleuronectites* thus far examined lack antimarginal microsculpture throughout ontogeny, indicating that these are an unlikely phylogenetic source for the earliest *Camptonectes*, which have fine but persistent antimarginal microsculpture. The earliest *Camptonectes* thus far reported are Late Triassic (Carnian-Norian) in age and are from the Boreal-East Asian Province of Japan and eastern Siberia (Hayami 1989: 6). Their likely origin is in the Triassic *Chlamys* group, possibly in the genus *Praechlamys* Allasinaz, 1972. *Delectopecten*, as a phyletic descendant of *Camptonectes*, thus still remains as the sister group of all other extant Pectinidae, but the divergence point should now be dated from the early Late Triassic (Carnian), in the time range of approximately 225 to 230 million years ago (Harland et al. 1990).

1.2.2 Subfamily Palliolinae Korobkov in Eberzin, 1960

The subfamily Palliolinae is used here in a phylogenetic sense for the monophyletic assemblage of genera (Fig. 1.2) rooted in *Dhondtichlamys* Waller, 2001 (replacement name for *Microchlamys* Sobetski, 1977; see Appendix Note 1). This genus, based on the type species *Pecten pulchellus* Nilsson, 1827, originated in the mid-Cretaceous from a *Chlamys*-like ancestor probably in the genus *Lyrionchlamys* Sobetski, 1977 (Waller 1991: 14). The time of origin is not certain but may have been Albian, based on the oldest

record of *Dhondtichlamys* given by Dhondt (1972: 8, for *Pecten (Aequipecten) arlesiensis* Woods, 1902).

The major morphological innovations in the shell of *Dhondtichlamys* involve shell microstructure, shell sculpture, and shell shape. (See Dhondt 1972, for good figures of *Dhondtichlamys* species under the combination "*Lyropecten (Aequipecten)*"). Compared to *Lyriochochlamys*, the leading edge of the inner crossed-lamellar aragonitic ostracum of *Dhondtichlamys* is withdrawn from the shell margins and hinge region and is restricted to an area that is mainly inside the pallial line. The microstructure of the foliated calcite of *Dhondtichlamys* between the pallial line and the margin is irregularly foliated. In this configuration, small patches of laths of uniform orientation produce tiny, reflective surfaces on the inner surface of well-preserved shells in contrast to the distinctly more uniform reflective surface of the corresponding region in most members of the *Chlamys* group. The contrast between these types of reflective surfaces may be observed by comparing palliolinine-type shells such as those of *Placopecten magellanicus* or "*Palliololum*" *tigerinum* (Gmelin, 1791) with shells of the *Chlamys* group such as those of *Chlamys islandica*, *Aequipecten opercularis*, or *Argopecten irradians*. Carter (1990: 297, and references therein) provided a detailed descriptive terminology for shell microstructures in the Bivalvia. For the purposes of the study, however, these two types of foliated calcite distinguished by the complexity of their reflective surfaces on the inner shell surface will be referred to as irregularly foliated and regularly foliated.

Both shell shape and radial macrosculpture are highly variable in Cretaceous *Dhondtichlamys*. In general, however, this genus, compared to coeval Cretaceous *Lyriochochlamys*, is characterised by its smaller size, somewhat broader umbonal angle, smaller auricles relative to size of disk, and stronger radial plicae that are wider than interspaces on the right valve and narrower than interspaces on the left valve due to interlocking of the plicae at the ventral margin. After an ontogenetically early scaly or reticulate phase in which scales form atop ribs and commarginal lirae cross both interspaces and ribs, the rib crests become smooth. Antimarginal microsculpture that is relatively coarse for the small shell size forms in a uniform continuous antimarginal pattern in the rib interspaces but is absent from the rib crests. The antimarginal ridglets strengthen considerably where they cross the disk flanks and extend onto the bases of the auricles. The auricles themselves vary in relative lengths from nearly equal to unequal with the anterior auricle the longer.

Dhondtichlamys survived the end-Cretaceous mass extinction and is the earliest coarsely ribbed pectinid to be found in the Paleocene. The specimens that I have been able to examine directly belong to two possibly intergradational species, *Dhondtichlamys johnsoni* (Clark, 1895) and *D. greggi* (Harris, 1897), from the Upper Paleocene (Thanetian) and Lower Eocene (Ypresian) of the Gulf Coastal Plain of southeastern United States (see Palmer and Brann 1965, for stratigraphic and geographic data). These species resemble Cretaceous *Dhondtichlamys* in shell microstructure, shape, ribbing style, and microsculpture. Like some Cretaceous species, the lengths of the anterior and posterior auricles of the Paleocene forms are nearly equal, and the posterior margin of the posterior auricles is convex outward.

In Figure 1.2, *Microchlamys* (= *Dhondtichlamys*) is shown as the ancestral group for four major evolutionary radiations that comprise single tribes or pairs of tribes as follows: (a) Pseudentoliini, new tribe, plus Adamussiini Habe, 1977; (b) Eburneopectinini, new tribe; (c) Serriopectinini, new tribe, and (d) Palliolini Korobkov in Eberzin, 1960, plus Mesopeplini, new tribe. The evidence for this phylogeny draws heavily on changing morphology within stratigraphic successions within geographic regions. Clear separation of the origins of similar morphologies in space and time provides strong evidence that these morphologies are convergent. This permits the disassembly of certain overly broad form genera, the outstanding example in this subfamily being *Eburneopecten* Conrad, 1865. Discussion of these clades begins at the left side of Figure 1.2 and proceeds to the right. In some cases, I continue to use a current genus-group name in quotation marks, indicating that this taxon can no longer be regarded as that genus but has not yet been renamed.

1.2.2.1 Tribe Pseudentoliini, new tribe

The new tribe Pseudentoliini is defined as a monophyletic group of genera rooted in "*Eburneopecten*" *frontalis* (Dall, 1898) (Appendix Note 2) of late Paleocene (Selandian, Thanetian) age in the North Atlantic. As presently understood, evolution from this root led successively through a series of morphologies represented by *Pseudentolium corneoides* (Harris, 1919), *Pseudentolium corneum* (J. Sowerby, 1818), and a succession of species in the genus *Korobkovia* Glibert and van de Poel, 1965. From the beginning of the Ypresian, the tribe was, so far as known, restricted to the seas of Europe and Asia and remained restricted to the Northern Hemisphere until its extinction at the end of the Pliocene.

At the base of this clade (A2 in Fig. 1.2), "*Eburneopecten*" *frontalis*, from the Upper Paleocene and Lower Eocene of Maryland, has the basic shape of Paleocene *Dhondtichlamys* and shares similar auricular costae and byssal fasciole. However, in contrast to the coarse plicae and strong antimarginal microsculpture of *Dhondtichlamys*, "*E.*" *frontalis* has nearly obsolete but ontogenetically continuous low, broad radial ribs and very fine antimarginal microsculpture. "*E.*" *frontalis* is closely followed stratigraphically by *Pseudentolium corneoides* in the early Ypresian of the North American Gulf Coast (A3, Fig. 1.2). This species, previously assigned to *Eburneopecten* (Palmer and Brann 1965: 134), is placed here in *Pseudentolium* because it displays distinctive features that characterise the taxa above Node A3. These features are associated with an evolutionary trend toward an amussioid adaptive form: a broad, low radial ridge on the inner surface of the disk inside each disk flank, disk gapes, auricular buttresses ending in low tubercles, a shallowing of the byssal notch, a reduction on the ontogenetic persistence of an active ctenolium, the formation of margins of the left auricles and of the right posterior auricle that form obtuse angles with the hinge line, and the complete loss of auricular costae. At Node A4, *Pseudentolium corneum* of the European Eocene and Oligocene evolved a distinctive flattened byssal fasciole and rounded shallow byssal notch with the functional ctenolium becoming obsolete before maturity. The nearly circular arc of the anterior margin of the right anterior auricle of this

species is nearly identical to that of *Korobkovia*. Principal innovations at Node A5 that characterise *Korobkovia* are shortened auricles relative to disk length, a trend toward narrowing of the disk, increased size of disk gapes, obsolescence of the byssal notch, and low radial ribs expressed mainly on the interior surface the left valve. These features of *Korobkovia* developed progressively within the genus as exemplified by the European stratigraphic succession of *K. denudata* (Reuss, 1867) of the Burdigalian and Langhian, *K. woodi* (Nyst, 1861) of the Serravallian, and *K. oblonga* (Philippi, 1844) of the Upper Miocene and Pliocene.

1.2.2.2 Tribe Adamussiini Habe, 1977

Habe (1977) introduced the subfamily Adamussiinae to contain only the genus *Adamussium* Thiele, 1934, which he regarded as being different enough from all other Pectinidae to justify this elevated rank. In the present study the name is reduced in rank to the tribal level within the subfamily Pallioliinae but is expanded to include phylogenetically related genera. The tribe is defined phylogenetically as rooted in the "*Eburneopecten*" *solea* group beginning in the Thanetian in Europe (A6, Fig. 1.2) and giving rise in the Southern Hemisphere to *Duplipecten* Marwick, 1928, and *Lentipecten* Marwick, 1928, in the Lutetian and to *Adamussium* in the Oligocene (possibly Chattian) (A7 to A10, Fig. 1.2). The last genus is extant in the antarctic region.

The oldest taxon included here in the "*E.*" *solea* group is "*Eburneopecten*" *breviauratum* (Deshayes, 1824), from the Thanetian of the Paris Basin, France. In shape and size it resembles coeval "*Eburneopecten*" *frontalis* of the American Thanetian but with two important differences: (a) the ribbing of the European species is much finer and begins later in ontogeny after a non-costate post-prismatic stage; and (b) the antimarginal microsculpture of the European species is plesiomorphically coarser. Other species that are probably members of this group that have ontogenetically late-appearing radial costae are all Lutetian in age and are possibly synonymous. These are "*E.*" *laekeniensis* (G. Vincent, 1881) from Belgium, "*E.*" *paueri* (Frauscher, 1886) from Germany and France, and "*E.*" *bourdoti* (Cossmann and Pissaro, 1903) from the Lutetian of France. All of these differ from Thanetian "*E.*" *breviauratum* in having even later appearing radial costae, broader umbonal angles, steeper disk flanks, a deeper byssal notch with a persistent active ctenolium, antimarginal microsculpture that is finer in the centre of the disk with commarginal shingles or fine commarginal lirae of low relief. They also differ in having broader disk gapes and low auricular buttresses ending in tubercles. The tubercle of the right anterior buttress forms along the margin of the disk flank distal to the byssal notch, not proximal to the byssal notch as in the Pseudentoliini. Plesiomorphic features include nearly equal lengths of anterior and posterior auricles, and a posterior auricular margin that is outwardly convex with its overall trend either nearly at a right angle to the hinge line or forming a slightly obtuse angle. "*E.*" *solea* (Deshayes, 1830) from the Lutetian of Belgium has this same suite of characters except for the late-appearing radial costae, which here are absent altogether, although its right anterior auricle still retains low radial costae.

The basis for the inference that the Southern Hemisphere genera *Duplipecten*, *Lentipecten*, and *Adamussium* share an ancestor rooted in the “*E.*” *solea* group is based on the presence of the characters mentioned above in the early ontogeny of both *Duplipecten* and *Lentipecten*. Both of these genera develop steeply intumed disk flanks in their right valves, with the point of inflection being a sharp edge separating the disk from the disk flank, and both show hypertrophy of a right anterior tubercle that forms distal to the byssal notch (not proximal as in *Pseudentolium*). It is likely, however, that these genera each originated from a common ancestor (A7, Fig. 1.2) rather than one from the other. Both appear at about the same time in the Bortonian stage (upper Lutetian) of New Zealand (Beu and Maxwell 1990). *Duplipecten* (A8, Fig. 1.2) evolved very deeply intumed disk flanks, particularly on its right valve, as well as autapomorphic low costae limited to the early ontogeny of its left valve. *Lentipecten* (Node A9), on the other hand, evolved amussioid features, with originally intumed, sharp-edged disk flanks reduced to mere sutures between the auricular and disk surfaces, more prominent internal auricular buttresses and tubercles, and restriction of the functional ctenolium to early ontogeny. *Adamussium* (A10, Fig. 1.2) is tied to the other members of the Adamussiini by its nearly equal auricles, the outwardly convex margins of its posterior auricles, and by its microsculpture, in which fine commarginal lirae interrupt the sweeping continuity of antimarginal striae. The regularity of this microstructural pattern is particularly close to that of *Lentipecten*, as shown by Beu and Dell (1989), who found a nearly morphologically intermediate fossil taxon preserved in the upper Oligocene (Chattian) level of a drill core from the Antarctic Ocean. Lastly, *Lentipecten* and *Adamussium* share a similar degree of extension of the prismatic stage of the right valve, to a height of 6 or 7 mm, that is higher than other members of this or of other clades in the subfamily.

Clearly many of the features of *Adamussium* are autapomorphies related to its extremely cold environment in Antarctica. Its shell is paper thin, and the low radial plicae are likely secondary features that serve to strengthen its shell. It lacks the amussioid auricular denticles of its hypothesised *Lentipecten* ancestor, but this may again be a secondary loss related to the difficulty of calcification in such a harsh environment.

1.2.2.3 Tribe *Eburneopectinini*, new tribe

Hertlein (1969: N352) used the term “*Eburneopecten* group” for an assemblage of 13 genera and subgenera having small, smooth shells, some without a ctenolium. He specifically stated that the relationships of these taxa “are not fully known”. Indeed, the members of this heterogeneous assemblage are now distributed among three families (Propeamussiidae, Entoliidae, and Pectinidae). Vaught (1989: 119), in a compendium of classifications of living Mollusca that provided no descriptions or analyses, used “Tribe *Eburneopectinini*” [sic] for Hertlein’s polyphyletic group. However, because she was concerned only with living taxa, *Eburneopecten*, an extinct genus, was omitted from her list. Her use of a tribal name for this group is here regarded as a *nomen nudum* (ICZN 4th Edition: Article 13 and p. 111).

In the present study, the tribe *Eburneopectinini* is limited to the genus *Eburneopecten* because of morphological and stratigraphic evidence that this genus evolved from

coarsely ribbed *Dhondtichlamys* in the early to mid-Eocene of eastern North America and is phylogenetically independent of so-called “*Eburneopecten*” in Europe (Fig. 1.2, Node E1 compared to A6). Well-preserved specimens of *E. scintillatus* consistently display fine radial costellae on the left beak that are ontogenetically decoupled from later costae that may appear near the ventral margin. The species retains costae throughout ontogeny on its right anterior auricle, whereas the costae on other auricles are absent or limited to early ontogeny. Similar decoupling of ribbing occurs within the range of variation of two older species that resemble *E. scintillatus*, and they are included here in *Eburneopecten*. One of these is *E. clarkeanus* (Aldrich, 1895) from the Cook Mountain Formation of Alabama of Bartonian age; the other is *E. burlesonensis* (Harris, 1919) from the Weches Formation of Texas of middle Lutetian age. The latter, older species resembles *Dhondtichlamys* in having strong steep-sided plicae but differs in having much finer antimarginal microsculpture in the rib interspaces. Both of these species exhibit great variation in the degree of rib interruption, with some specimens approaching the nearly smooth condition of *Eburneopecten scintillatus*. (See illustrations of these species in Harris 1919, pl. 14, figs. 11–13 and pl. 15, figs. 8–13.)

1.2.2.4 Tribe *Serripectinini*, new tribe

The new tribe *Serripectinini* is defined phylogenetically as a monophyletic group of genera beginning with a morphology represented by “*Chlamys*” *choctavensis* (Aldrich, 1895) of the early Ypresian of southeastern United States (S1, Fig. 1.2) and leading to the genera *Batequeus* Squires and Demetron, 1990 (Lutetian, Baja California, Mexico; S3 in Fig. 1.2), *Serripecten* Marwick, 1928 (Ypresian to Tortonian of New Zealand; S4 in Fig. 1.2), and *Janupecten* Marwick, 1928 (Priabonian to Chattian, New Zealand; S5 in Fig. 1.2). The age ranges are taken from Beu and Maxwell (1990: 33–34) but translated into European stage names via their correlation chart (their fig. 1).

“*Chlamys*” *choctavensis* retains the shape and smoothness of primary plicae present in *Dhondtichlamys* and has the same pattern of coarse antimarginal striae restricted to rib interspaces. As in the *Dhondtichlamys greggi-johnsoni* lineage (see above), “*C.*” *choctavensis* has anterior and posterior auricles of nearly equal length, a deep byssal notch, and an ontogenetically persistent active ctenolium. Morphological characters that tie “*C.*” *choctavensis* with *Batequeus*, *Serripecten*, and *Janupecten* (Node S1, Fig. 1.2) are its broadened umbonal angle, lower convexity of both valves (still retaining a biconvex condition), incipient disk gapes, auricular tubercles (the left anterior tubercle present, other tubercles weak or absent), and, most importantly, the medial intercalation of secondary costae in rib interspaces in mid to late ontogeny on both valves. This species also shows the start of sculptural differences between the two valves in that the anterior and posterior ribs of the left valve develop erect cusped scales beginning early in ontogeny, these being absent on the right valve. There is a very close resemblance between “*C.*” *choctavensis* and “*Serripecten*” *tiorioriensis* Marwick, 1928, a species that occurs in rocks of approximately the same age (late Paleocene and/or earliest Eocene) in New Zealand. Beu and Maxwell (1990: 88) referred to this species as “the oldest known species of [*Serripecten*]”, noting that it differs from later members of the genus by its

smaller size and its simpler radial sculpture, radial ribs that are smooth-crested, and the late appearance of secondary ribs. Other species that possibly represent early *Serripecten* have been described by Maxwell (1992) from the Bartonian (late Lutetian) stage of New Zealand.

Node S2 (Fig. 1.2) represents the start of extreme differential sculpture of the two valves, that of the left valve being densely costate, with all of the costae scaly, that of the right valve having only the coarser primary plicae and intercalated secondaries. *Batequeus* (Node S3) retains plesiomorphic biconvexity (Squires and Demetron 1990, fig. 2(3)) while evolving medial bifurcation of its central right primary plicae. Thus far *Batequeus* is known only from its type species, *B. mezquitalensis* Squires and Demetron, 1990, from the Bateque Formation of Baja California Sur, Mexico. Its age was originally given as middle Eocene based on planktonic foraminifera indicating zones P8 or P9 of Berggren et al. (1985). However, those zones now indicate a late Early Eocene age (late Ypresian) according to Berggren et al. (1995: 140). A second species of *Batequeus*, *B. ducenticostatus* Campbell, 1995, from the "Cross Formation" of probable Bartonian age of South Carolina, is not a *Batequeus* but rather is a member of the *Chlamys* group. Its radial sculpture is similar on the two valves, and its radial costae are more densely packed, more densely scaly, and with a more complex introduction pattern throughout ontogeny than in any member of the *Batequeus-Serripecten* clade.

Node S4 marks the start of an ontogenetic trajectory of increasing valve convexity so that maximum convexity is near the mid-point of the dorso-ventral dimension. This node also marks the steepening and actual inturning of the disk flanks, particularly those of the right valve. Both *Serripecten* and *Janupecten* have low, broadly trigonal plicae on the right valve. *Serripecten* develops distally pointed scales on these plicae, with the scales becoming distinctly skewed toward the outside near the anterior and posterior margins of the disk. Its differential sculpture, with costae more numerous and more scaly on the left valve than on the right, is shared with *Batequeus*.

Janupecten (S5, Fig. 1.2) was originally named as a subgenus of *Serripecten* by Marwick (1928: 455), but Hertlein (1969: N363) regarded the former as a junior synonym of the latter. The close relationship of *Janupecten* to *Serripecten* is indicated by remnant outwardly skewed scales atop the anterior and posterior ribs of the right valves observable on well-preserved specimens of *Janupecten polemicus* Marwick, 1943, and *J. uttleyi* (Marwick, 1928). On less well-preserved specimens, the exterior features on rib crests are obliterated by corrosion that is limited to the rib crests while the rib interspaces remain intact. Commonly, this corrosion is extensive enough so that the ribs may appear depressed below the level of the adjacent interspaces. This differential stability between rib crests and rib interspaces appears to be the result of a less stable shell microstructure present along the rib crests just interior to a very thin outer calcitic layer. This microstructure, which has not yet been investigated by scanning electron microscopy, turns chalky even before the thin exterior layer is breached, causing the ribs of some specimens to appear as white rays. Cross sections through the ribs show that the chalky material is restricted to a lenticular area beneath the rib crest. This unusual structure is regarded as an autapomorphy of *Janupecten*.

1.2.2.5 Tribe Palliolini Korobkov in Eberzin, 1960

The tribe Palliolini is rooted in *Palliolum* Monterosato, 1884, and contains the derivative genera *Placopecten* Verrill, 1897, *Karnekampia* Wagner, 1988, and *Pseudamussium* Mörch, 1853, all of which are endemic to the North Atlantic. Representative extant species are *Palliolum striatum* (Müller, 1776), *Placopecten magellanicus* (Gmelin, 1791), *Karnekampia sulcata* (Müller, 1776), and *Pseudamussium septemradiatum* (Müller, 1776). The tribe is paraphyletic because of the exclusion of the tribe Mesopeplini, new tribe, a closely knit group of five Southern Hemisphere genera with a morphological link to the Palliolini (see below).

A morphological definition of the Palliolini is difficult, because its constituent genera are among the most variable known in the Pectinidae. Like all members of the subfamily Palliolinae, members of the tribe Palliolini have irregularly foliated calcite in the ventral shell region outside the pallial line and differ in this respect from *Chlamys*. Perhaps the best morphological definition of the Palliolini that can be ventured is that the tribe consists of genera that have costate auricles but commonly either lack radial ribs on the disk, in which case the surface is dominated by coarse antimarginal microsculpture, or have primary ribbing in the form of numerous low costae. The higher magnitude plicae that occur in most taxa (above Node P2 in Fig. 1.2) are secondary, commonly arising by the merger of primary costae in early ontogeny. All but the more primitive members of the group have posterior auricles with an outwardly concave posterior margin at least in early ontogeny. Because of the secondary origin of the highest order ribs, ribbing style is enormously variable in spacing, ordering, and magnitude. Members of this group are generally chlamydoid in shape, with a deep byssal notch and persistent functional ctenolium, but some lineages evolved amussioid and pectinoid forms. The two best-known amussioid examples are *Palliolum gerardi* (Nyst 1835) in the Pliocene of the North Sea Basin in Europe (Janssen and Dijkstra 1996: 112), and the genus *Placopecten* in the Upper Miocene to Recent of eastern North America. Pectinoid form is exemplified by *Hilberia* von Teppner, 1922.

Palliolum is regarded here as the stem genus of the tribe. Among its oldest species are *Palliolum prestwichi* (Morris, 1852) from the Thanetian, *Palliolum vincenti* (Glibert 1933) from the lower Lutetian, *P. nysti* (G. Vincent, 1881) from the middle Lutetian, and *P. decussatum* (Münster in Goldfuss, 1833) from the Rupelian, all of which occur in northern Europe. Fossil species of the extant species *Palliolum incomparabile* (Risso, 1826) have been reported from rocks as old as Chattian (Báldi 1973: 183). Collectively these fossil species have posterior auricles that are shorter than the anterior ones in length and have convex to nearly straight posterior auricular margins that tend to form obtuse angles with the hinge. If radial costae are present on the disk, they are fine and numerous and tend to be continuous from early ontogeny. In these costate forms, coarse antimarginal striae commonly cross over the costae rather than being restricted to rib interspaces as in *Dhondtichlamys*. All auricles are multicostate regardless of whether costae are present on the disk. The extant species *Palliolum striatum* and *P. incomparabile* retain most of these ancestral features. The latter is the type species of the genus (subsequent designation by Crosse; see Hertlein 1969: N354).

All higher members of the Pallioliini are united at Node P2 (Fig. 1.2) by (a) shared ribbing complexity, including the secondary major plicae mentioned above, and (b) increasing complexity of antimarginal striae in rib interspaces, commonly producing a “pseudoshagreen” microsculpture in very limited areas of the disk where not masked by other microsculpture. With the exception of *Hilberia*, all of the genera above this node also have at least some members that display third-order very fine costellae that are hardly greater in width than are the adjacent antimarginal striae. In the more primitive members of *Hilberia*, e.g., *H. hoeninghausi* (Defrance, 1825: 256), very coarse antimarginal ridgelets are present in a complex pattern in rib interspaces in early ontogeny.

At Node P4 (Fig. 1.2) the extant taxa “*Palliolium*” *tigerinum*, *Karnekampia*, and *Pseudamussium* are united by substantial auricular asymmetry, with the posterior auricles shortened relative to the length of the anterior auricles, and by the distinctly concave posterior margins of the posterior auricles, the presence of coarse radial costae on the left anterior auricle that produce a dentate anterior margin, and the presence of enlarged commarginal auricular lamellae on at least the basal part of the left anterior auricle. At least some populations in all of these groups also show the presence of large radial folds, although these may be highly variable in amplitude and number. The auricles of mature *Hilberia* are of nearly equal length, but they attain this symmetry secondarily during ontogeny. In juvenile shells of *Hilberia* the shorter posterior auricle has a distinctly concave posterior margin.

At Node P5 (Fig. 1.2) *Hilberia*, *Karnekampia*, and *Pseudamussium* are united by the presence of commarginal lirae in rib interspaces, these lirae being regularly spaced but of irregular commarginal trend. Their intersections with the fine radial costellae that are present in the earliest ontogeny of the left valve produce a finely reticulate pattern on the left umbo. The lirae tend to persist throughout ontogeny in *Karnekampia* and the more primitive species of *Hilberia*; in *Pseudamussium* the lirae disappear in later ontogeny either as part of a general smoothening of the shell or because they are masked by a complex microsculpture (see below). These genera also share a peculiar scale morphology. Each scale is enlarged but distally directed along the rib crest, commonly merging with the succeeded scale as well as extending laterally somewhat beyond the sides of each rib. These types of scales are present in *Hilberia hoeninghausi* (particularly on the right valve), in *Karnekampia*, and on the right valves of *Pseudamussium*.

At Node P6 (Fig. 1.2), *Hilberia*, comprising a cohesive set of species limited to the Nordic and Atlantic basins of Europe in the latest Eocene through Oligocene (Roger 1944; Anderson 1958), evolved a pectinoid form, with a convex right valve and flat left valve and a correlated set of changes leading to a non-functional ctenolium, very rounded byssal notch, equal length of auricles, basal auricular buttresses on the shell interiors, and inturned disk flanks. Unlike true *Pecten*, none of the species with strong radial plicae developed internal rib carinae and the hinge teeth are simple, with dorsal teeth dominant and resilial teeth poorly developed. As in all members of the subfamily Pallioliinae thus far studied in detail, *Hilberia* has irregularly foliated calcite outside the pallial line in the central sector of the shell.

At Node P7 (Fig. 1.2), *Karnekampia* and *Pseudamussium* share the common presence of a pseudosurface formed by the side-to-side merger of fine third-order costellae that are

T-shaped in cross section. This microsculptural feature is common in the more southerly populations of species in both genera, whereas in more northerly populations its presence is variable within population samples. Although comparable costellae occur in both *Placopecten* and "*Palliolium*" *tigerinum*, their side-to-side merger has not been observed in *Placopecten* and occurs only very rarely in "*P.*" *tigerinum*. Lastly, at Node P8 *Pseudamussium*, represented in the present-day northeastern Atlantic and deep Mediterranean by *P. septemradiatum* and the possibly intergradational *P. clavatum* (Poli, 1795), is distinguished by its very shallow byssal notch (depth about one fourth or less the length of the anterior auricle compared to half the length of the auricle in *Karnekampia*), a ctenolium that is barely functional at maturity (compared to a strong and persistent functional ctenolium in *Karnekampia*), and five to seven large radial folds.

Except for the *Placopecten* clade (P3 in Fig. 1.2), the branching points of the phylogeny described above are corroborated by the relative times of known first occurrences in the fossil record. As stated above, the P1 lineage (*Palliolium*) is represented by fossils in the Thanetian and Lutetian. The main diversification of the tribe appears to have occurred in the Oligocene at a time of global cooling. A probable early member of the "*Palliolium*" *tigerinum* lineage in the Rupelian of Germany was originally described in the combination *Chlamys* (*Flexopecten*) *welschbergensis* Neuffer, 1973. But the published figures (Neuffer 1973, pl. 5, figs. 10–12) display the characters described above for Node P4. *Karnekampia* was also present by Rupelian time, an example being the species from the Rupelian of Germany identified by Neuffer (1973:37, pl. 5, figs. 18, 19) as *Chlamys* (*Chlamys*) *striatocostata* (Münster in Goldfuss, 1833). Specimens of this species reported by Glibert (1957:20, pl. 1, figs. 15a–d) from the Chattian of Belgium were examined by the author. They have the third-order T-shaped costellae and commarginal lirae that mark Node P6, and Glibert remarked on the probable relationship of this species to *Peplum* Bucquoy, Dautzenberg, and Dollfus, 1889, a genus now regarded by most malacologists as a junior synonym of *Pseudamussium*. *Karnekampia* proliferated during the Miocene in the North Sea Basin with the appearance of *Karnekampia lilli* (Pusch, 1837), a highly variable species with many subspecies, "varieties", and synonyms (Glibert 1945: 73; Marquet and Dijkstra 1999; and references therein). *Pseudamussium*, the youngest branch in the phylogeny, is not known in the fossil record before the Tortonian (Roger 1939: 214).

The position of *Placopecten* in the phylogeny of the Palliolineae is based on the demonstration of morphological transition between members of this genus and the fossil species "*Chlamys*" *decemnaria* (Conrad, 1834) by Gibson (1987: 68). At one end of its spectrum of variation "*C.*" *decemnaria* is chlamydoid in form, with a complex ribbing pattern beginning ontogenetically with fine costellae that merge and cluster into coarser secondary plicae. This ribbing pattern, coarse antimarginal microsculpture between the ribs and across the disk flanks, and limited areas of "pseudoshagreen" microsculpture on the disk resemble features that are present in "*Palliolium*" *tigerinum* and higher lineages in the phylogeny (Fig. 1.2). At the other end of the spectrum of variation, "*C.*" *decemnaria* approaches the shape and ribbing style of typical *Placopecten*, including the fossil species *P. clintonius* (Say, 1824), *P. princepoides* (Emmons, 1858), and *P. sp. aff. P. magellanicus* (Gibson 1987; see also Appendix Note 3). Given this transition, it is

reasonable to place "*Chlamys*" *decemnaria* in the genus *Placopecten* (in the combination *Placopecten decemnarius*) and to expand the concept of *Placopecten* to include chlamydoid forms that show variation into *Placopecten*-type morphology. The reason that *Placopecten* in this expanded concept is placed as a sister group of the clade that originates at Node P4 (Fig. 1.2) rather than being a member of that clade is because of differences in auricular shape and auricular sculpture. The posterior margins of the posterior auricles of *Placopecten decemnarius* and other species of the genus are plesiomorphically straight or convex, not concave as at Node P4, and they lack the other auricular character states mentioned above for Node P4.

A difficulty with the phylogenetic position of *Placopecten* shown in Figure 1.2 involves the relative stratigraphic positions of *P. decemnarius* and the more typical members of the genus. The earliest species known is *P. princepoides*, which occurs in the Eastover Formation of Virginia in strata that are of late Tortonian age (Ward 1992: 4, 66). This species already has a broad nearly smooth shell with shallow byssal notch and obsolete ctenolium comparable to these features in extant *P. magellanicus*. Even though *Placopecten decemnarius* is more plesiomorphic, it has thus far been found only in the stratigraphically higher Yorktown Formation of Virginia of Pliocene age. A possible explanation of this discrepancy involves the completeness of the fossil record in the Atlantic Coastal Plain of eastern North America. Because *Placopecten* occurs near the northern limit of the Eastover and Yorktown Formations and because older formations to the north may represent shallower facies, it may be that its fossil history is simply not preserved. On the basis of the phylogeny as currently understood, *Placopecten* probably originated from an eastern Atlantic ancestral species. Curiously, one of the few living northeastern Atlantic species that occurs in the northwestern Atlantic is *Palliolium striatum*, based on USNM 764670, a specimen dredged from 192 m off Cape Cod, Massachusetts, in 1936.

1.2.2.6 Tribe Mesopeplini, new tribe

The new Tribe Mesopeplini is erected to contain a phylogenetically closely knit group of five pallioline genera and one subgenus (Fig. 1.2, Nodes M1-M6), all of which are endemic to New Zealand and Australia (Beu 1978, 1995; Beu and Maxwell 1990): *Mesopeplum* (*Mesopeplum*) Iredale, 1929, Bartonian?, Chattian to Recent, New Zealand and Australia; *Mesopeplum* (*Borehamia*) Beu, 1978, Messinian to early Piacenzian, New Zealand only; *Sectipecten* Marwick, 1928, Serravallian to latest Pliocene, New Zealand and Chatham Islands; *Phialopecten* Marwick, 1928, Messinian to late Pliocene, New Zealand only; *Kaparachlamys* Boreham, 1965, late Pliocene, New Zealand and Chatham Islands; and *Towaipecten* Beu, 1995, latest Pliocene and earliest Pleistocene, New Zealand only. The only extant genus, *Mesopeplum* (*Mesopeplum*), is represented in present-day oceans by *M. (M.) caroli* Iredale, 1929, of southeastern and southern Australia and by *M. (M.) convexum* (Quoy and Gaimard, 1835) of New Zealand and the Chatham Islands. Reports of *Mesopeplum* in the Eocene and Oligocene of Argentina by Morra and Erdmann (1986) refer to giant members of the Chlamydiae that bear shagreen microsculpture and are therefore excluded from the Palliolineae.

Collectively, this group displays a higher level of variation in ribbing patterns and shell shapes than almost any other group of Pectinidae. What ties these genera together are demonstrations of morphological transitions in carefully collected stratigraphic sequences. These transitions and occurrences have been discussed in detail in a series of remarkable monographs by Beu (1978), Beu and Maxwell (1990), and Beu (1995). The relationships of these genera depicted in the phylogeny in Figure 1.2 (Nodes M1–M6) are based upon these works and my own examination of specimens representing all of the genera except *Kaparachlamys* and *Towaipecten*.

Mesopeplum (*Mesopeplum*) is the basal genus of the tribe (Beu 1995: 186), a conclusion that is supported by its morphology and its lowest stratigraphic occurrence. It shares with the *Karnekipia-Pseudamussium* clade (P5, Fig. 1.2) the presence of radial costae that are clustered in broad radial folds, posterior auricles with a distinctly concave posterior margin, auricular asymmetry (posterior auricle shorter than anterior auricle in primitive members), and commarginal lirae in costal interspaces. In all members of the Mesopeplini (Node M1), the commarginal lirae, which are present only in early ontogeny below Node M1, are present throughout ontogeny and in more derived genera may be extended into commarginal frills. A limited number of broad radial folds, generally five, is also present at least in the early ontogeny of primitive *Mesopeplum* (*Borehamia*), *Sectipecten*, and *Phialopecten* (Beu 1995: 32, 255) but more even ribbing patterns prevail in more derived forms. The evolution of *Sectipecten* from *Mesopeplum* (*Borehamia*) (Node M3) was discussed by Boreham (1961) and by Beu (1995: 55). All of the genera of Mesopeplini above Node M4 develop internal rib carinae, the only occurrence of this character within the subfamily Palliolineae. These carinae are readily apparent in *Phialopecten* but less so in *Towaipecten*, where plicae disappear in late ontogeny, and in *Kaparachlamys*, where the internal rib carinae are vestigial (limited mainly to the lateral areas of the inner disk surface). The secondary approach toward very fine external costation and smoothness, as well as shortening of auricles, and reduction in depth of the byssal notch, give *Kaparachlamys* a *Placopecten*-like appearance. Marwick (1928: 451), Boreham (1965: 25), and Beu (1995: 19) all attributed this similarity to evolutionary convergence.

If the *Karnekipia-Pseudamussium* clade of the Palliolini and the tribe Mesopeplini shared a common ancestor in the early Oligocene as indicated at Node P4 (Fig. 1.2), the diversification of these groups may be related to the cooling of the world's climate at that time. This may have allowed the spread of pallioline taxa that had previously been confined to higher northern latitudes across the tropics into the Southern Hemisphere. The earliest occurrence of *Mesopeplum* in New Zealand, however, is still poorly known. Beu and Maxwell (1990: 338) reported that *M. (M.) convexum* (Quoy and Gaimard, 1835) may occur as early as Kaiatan Stage (= Bartonian, early Late Eocene) in New Zealand but also expressed uncertainty as to whether these early forms were a part of the same species lineage, the known stratigraphic range of which is from late Chattian to present.

1.2.3 Origins of the *Decatopecten* and *Pecten* Groups

Waller (1991: 15 and fig. 8; Fig. 1.1 herein) hypothesised a close relationship between *Pecten* Müller, 1776, and *Decatopecten* Rüppel in Sowerby, 1839, and suggested that the Decatopectinini may serve as a bridge between the *Pecten* group and the Palliolinae. *Amussiopecten* Sacco, 1897a, *sensu lato*, was shown as the basal member of the *Pecten* group in the Oligocene, leading to three separate clades represented by the extant genera *Amusium*, *Pecten*, and *Euvola* (Waller 1991, fig. 11). Subsequent studies of *Amussiopecten* and a search for its ancestors in the Eocene and Oligocene have led to new phylogenetic hypotheses (Fig. 1.3): Both the *Pecten* and *Decatopecten* groups are derived from an ancestral stock that in turn was derived from the *Aequipecten* group of Waller (1991). There is no close relationship between these groups and the Palliolinae. Furthermore, the *Decatopecten* group as originally defined is not monophyletic but rather consists of three extant components with separate origins: (a) *Decatopecten* and allied genera occurring mainly in the Indo-Pacific region (Waller 1986); (b) *Annachlamys* Iredale, 1939, occurring in the western Indo-Pacific region; and (c) *Flexopecten* Sacco, 1897a (including *Proteopecten* Monterosato, 1899, and *Lissopecten* Verrill, 1897), occurring in the Mediterranean and adjacent Atlantic. As indicated in Figure 1.3, the former *Decatopecten* and *Pecten* groups are now regarded as two separate monophyletic tribes, Decatopectinini and Pectinini, while the genera *Amussiopecten*, *Amusium*, and *Euvola* comprise a third monophyletic tribe Amusiini. Collective these three groups comprise the subfamily Pectininae.

A likely stem group of the Pectininae is the "*Pecten*" *perplanus* stock of Glawe (1969), an array of species and subspecies common in the Vicksburgian Stage of the Oligocene of southeastern U.S.A. Vicksburgian strata are now known to be equivalent in age to the Rupelian and early Chattian of Europe (Siesser 1984; Rossbach and Carter 1991). Both G.D. Harris (1951: 9) and Glawe (1969: 39) suggested that a probable ancestor of the *P. perplanus* stock in the Eocene is "*Pecten*" *elixatus* Conrad, 1844, said to be from the "Santee Limestone" of South Carolina (Glawe 1969: 39). The precise position of this fossil within limestone beds that have been called "Santee Limestone" is unknown and there is substantial confusion regarding the correlation of limestone units in this area (Campbell 1995). True Santee Limestone is generally regarded as Middle Eocene (middle Lutetian through Bartonian) in age (Palmer and Brann 1965; W.B. Harris et al. 1984), but it is possible that this species is from a later Eocene unit.

Glawe (1969), by plotting the frequency distribution of several morphotypes within stratigraphically successional population samples, showed that the "*Pecten*" *perplanus* stock during the early Oligocene split into two lineages, both derived from "*Pecten*" *perplanus perplanus* Morton, 1833. The first lineage evolved from this species to "*P.*" *perplanus poulsoni* Morton, 1834, to "*P.*" *perplanus byramensis* Gardner, 1945. The other evolved from "*P.*" *perplanus perplanus* to "*P.*" *howei mariannensis* Glawe, 1969, to "*P.*" *howei howei* (Mansfield 1940). The "*Pecten*" *perplanus* stock ended, so far as known, with the last occurrence of "*P.*" *howei howei* in the Chickasawhay Limestone and Paynes Hammock Formation of the American Gulf Coastal Plain in the late Rupelian or early Chattian (Glawe 1969: 57; Seisser 1984, fig. 3; Berggren et al. 1995: fig. 3).

Members of the "*Pecten*" *perplanus* stock have regularly foliated calcite in the midventral region outside of the pallial line, not the irregular foliation that is present throughout the Palliolineae. Their shell shape is generally biconvex and aequiptectinoid but with the left valve distinctly less convex than the right, especially in the basal members and in the *byramensis* lineage, where some individuals may approach a pectinoid form. The byssal notch is only moderately deep in the geologically older members of the stock and becomes more shallow in both lineages. In all members of the group, the ctenolium terminates before maturity, and all have strong internal buttressing ridges aligned with the bases of the auricles and ending in tubercles. Auricular costae are strong in early members of the stock and tend to remain so in the *byramensis* lineage, but they become obsolete or disappear within the *howei* lineage. All members of the *perplanus* stock have strong commarginal lamellae in a characteristic pattern described below. Microsculpture of the left beak is seldom preserved, but it appears to be smooth in later members of the stock. A specimen identified as "*P.*" *perplanus poulsoni* was found to have a transient pitted microsculpture in the late pre-radial stage of the left valve, suggesting that the smooth beaks of later members of the stock may be a derived condition. In the early radially plicate stage, very fine antimarginal striae may be present in rib interspaces between commarginal lamellae, but these disappear in later ontogeny. Finally, all members of the stock have well-developed internal rib carinae.

A link between the "*Pecten*" *perplanus* stock with *Aequiptecten* is indicated not only by the presence of strong internal rib carinae, but also by the trend of commarginal lamellae on the flanks of radial plicae in early ontogeny. In the early ontogeny of "*P.*" *perplanus perplanus* and some "*P.*" *perplanus poulsoni*, before the unilirate phase (see below), these lamellae form tight distally concave arcs on steep rib flanks, a pattern that is also commonly present in the early ontogeny of aequiptectine genera such as *Aequiptecten*, *Cryptopecten*, and some *Argopecten*.

Other characters found in the "*Pecten*" *perplanus* stock provide phylogenetic links to *Amussiopecten* and true *Pecten* (Fig. 1.3). Most members of the "*P.*" *perplanus* stock have three pairs of hinge teeth on the right valve, an elongate dorsal tooth on each side of the resilifer, a single intermediate tooth that is shorter but equally strong at least on the anterior side, and a weakly developed resilial tooth. Ontogenetically, the intermediate tooth differentiates from an early out-turned resilial tooth, first on the anterior side and later on the posterior side. A similar ontogenetic pattern leading to a three-element hinge dentition occurs in some fossil *Mimachlamys* and *Aequiptecten*, in some *Amussiopecten*, and in forerunners of true *Pecten*. In *Amussiopecten* this dentition pattern occurs mainly in the oldest members of this genus in the upper Oligocene, although it is retained in *Amussiopecten subpleuronectes* (d'Orbigny, 1852) and *A. burdigalensis* (Lamarck, 1806), which are, respectively, from the Aquitanian and Burdigalian of southern Europe. The latter species is the type species of the genus. Three-element dentition is also present in southern European species that have long been regarded as belonging in the ancestry of true *Pecten*: "*Pecten*" *arcuatus* Brocchi, 1814, from the late Eocene (Priabonian) and Oligocene (Rupelian and Chattian) (Depéret and Roman 1902: 10; Cossmann 1921: 167; Bongrain 1988: 189); "*P.*" *carryensis* Gourret, 1890, of the Aquitanian and possibly Burdigalian (Depéret and Roman 1910: 135; Roger 1939: 250); and some members of the

highly variable species *Oopecten rotundatus* (Lamarck, 1819) and *Pecten beudanti* Basterot, 1825, of the Aquitanian and Burdigalian (Roger 1939: 10, 240). Another character that ties the *perplanus* stock to these same taxa is unilirate rib sculpture (Glawe 1969), in which a single radial lira runs down the centre of each plica. The plicae are generally parabolic in cross section. Commarginal lamellae, which pass straight across the rib interspaces, pass up the curved flank of the rib in a broad distally concave arc, finally trending distally along the side of the narrow lira on the rib crest. This unilirate pattern may occur on either or both valves and may be limited to a short ontogenetic phase. A similar configuration is present in each of the extinct southern European species listed above as having three-element hinge dentition. Unilirate sculpture of the *perplanus* type seems to be absent from *Amussiopecten* and its derivatives, but presumably this absence is secondary, reflecting a general decrease in rib amplitude and a trend toward an amussioid adaptive form.

These characters provide the basis for the early part of the phylogeny of what will be called here the Tribe Pectinini (Fig. 1.3). "*Pecten*" *arcuatus* is regarded as the earliest known member of the tribe. This highly variable species of the Upper Eocene (Priabonian) and Oligocene (Rupelian and Chattian) of southern Europe has a thick, very inequivalved shell with strong simple plicae and a three-element hinge having prominent or even hypertrophied intermediate teeth. Its right valve is deeply convex; its left valve is highly variable in convexity, ranging from uniformly slightly concave, to overall convex but with a depressed ontogenetically early concavity, to uniformly concave (Bongrain 1988, pl. 17; Cossmann 1921). The forms that have ontogenetically early and temporary concavity of the left valve resemble later members of *Gigantopecten* Rovereto, 1899, that are well known for this feature, termed "coup de pouce" (thumb print) by Bongrain (1988: 56). "*Pecten*" *arcuatus* should probably be placed in this genus as its earliest member, a position implied in the detailed study of the genus by Bongrain (1988: 189). *Gigantopecten*, as its name implies (Appendix Note 4), reached gigantic size in its later phylogenetic history, becoming extinct in the late Pliocene. "*Pecten*" *arcuatus* had well developed commarginal lamellae, and on some specimens these combine with unilirate plicae to produce a sculptural pattern like that in the "*Pecten*" *perplanus* stock. As shown by Bongrain (1988), *Pecten beudanti* Basterot, a Burdigalian species that is regarded as the earliest true *Pecten*, resembles "*P.*" *arcuatus* in shell shape, and its left valve has coarse commarginal lamellae and incipient unilirate plicae. Unlike *arcuatus*, the hinge dentition of *P. beudanti* has weaker intermediate teeth that are commonly multiplied, a pattern that is found in extant *Pecten*. Beginning in the Burdigalian, true *Pecten* diversified rapidly and entered the Indian Ocean via the eastern gates of the Mediterranean before their initial closure at the end of the Burdigalian (Adams et al. 1990: 304; Rögl 1999: 343).

The diversification of true *Pecten* led repeatedly to forms with a right valve of only moderate convexity and a nearly flat left valve. These were assigned to a new subgenus *Pecten* (*Flabellipecten*) by Sacco (1897a, b) based on a Pliocene type species, *Pecten flabelliformis* (Brocchi, 1814). Depéret and Roman (1910: 106) mistakenly thought these later forms were the same as *Amussiopecten* Sacco, 1897, and chose to regard the latter subgenus as a junior synonym of the former even though *Amussiopecten* appeared first in Sacco (1897a).

Waller (1991: 38–39, fig. 11; Fig. 1.1 herein) emphasised the phylogenetic separation of true *Pecten* of the eastern Atlantic and western Indo-Pacific regions from *Euvola* of the Americas, both groups originating from the genus *Amussiopecten* in the Miocene. The new analysis outlined above increases the phylogenetic separation of these two groups by demonstrating an earlier origin for *Pecten* (Fig. 1.3). As in Waller (1991), both *Euvola* and *Amusium* are still regarded as derivatives from *Amussiopecten*, but new research on tropical American Tertiary pectinids now makes it possible to provide more detail on the *Amussiopecten-Euvola* relationship. The evidence lies in a stratigraphic succession of Central American species that lived during the Miocene when the Atlantic and Pacific were still connected by Central American seaways. Woodring (1982: 581) referred the taxa in this succession to his “*Flabellipecten gatunensis* group”, claiming that in Panama, “The group of *Flabellipecten gatunensis* can be traced through nine stratigraphic units, ranging in age from late Oligocene to late Miocene or Pliocene.” He regarded the first three taxa in this stratigraphic succession to be “an unbroken main lineage”, these taxa being “*Flabellipecten gatunensis protistus* Woodring, 1982, of the late Oligocene and early Miocene, followed by “*F.*” *gatunensis gatunensis* (Toula, 1909) of the early and middle Miocene, in turn followed by “*F.*” *gatunensis macdonaldi* (Olsson, 1922) of the late Miocene or early Pliocene.

Examination of specimens of all of these taxa has led to a different interpretation. The early members of this succession lack auricular costae and are thus unlike the European subgenus *Pecten* (*Flabellipecten*), which has multiple auricular costae tending to be evenly distributed across the auricles as in *Pecten s.s.* Later members of the Central American series exhibit a few weak, unevenly spaced auricular costellae, which may resemble in number and spacing the auricular costae in *Euvola*. Also unlike *Pecten* (*Flabellipecten*), all of the Central American taxa with the exception of the earliest one, “*Flabellipecten gatunensis protistus*”, lack intermediate hinge teeth. Instead, the dentition is dominated by dorsal teeth, thus resembling the hinge configuration of *Euvola* (Waller 1991: 38). It is only “*Flabellipecten gatunensis protistus*” that has intermediate hinge teeth, there being a single short but well differentiated one on each side of the right resilifer. The only significant difference between this taxon and typical Oligocene *Amussiopecten* is in ribbing persistence. In *Amussiopecten* the disk plicae during ontogeny fade out before reaching the margin of the disk (see Masuda 1971b). In “*F.*” *gatunensis protistus*, the distal fading of plicae is variable, as Woodring (1982: 583) indicated, and in some specimens the plicae persist throughout ontogeny.

Evolutionary trends within this Central American group include increasing persistence and amplitude of disk plicae and increase in adventitious auricular costae from a plesiomorphically non-costate state. These trends can be followed into the living eastern Pacific taxa “*Pecten diegensis* Dall, 1898, “*P.*” *sericeus* Hinds, 1845, and “*P.*” *stillmani* Dijkstra, 1998, taxa that Woodring (1982: 584) also recognised as being closely related and in the same group. The same features are present in a group of fossil species in the Upper Miocene and Pliocene of southern California and Baja California, Mexico, commonly referred to *Flabellipecten* (e.g., Moore 1984 and Smith 1991). Masuda (1971a) had earlier erected a new genus, *Leopecten*, for this group, choosing as type species *Pecten (Patinopecten) bakeri* Hanna and Hertlein, 1927, from the Lower Pliocene

of Baja California. This is an unusual endemic member of the genus because of its high degree of secondary radial costation, but clearly the name *Leopecten* should apply to the whole American "*Flabellipecten*" assemblage. Here I reduce *Leopecten* to the level of subgenus within *Euvola* because of the close phylogenetic linkage. Masuda (1971a: 171) anticipated Woodring's (1982) discovery of the succession of species linking *Amussiopecten* and *Leopecten* in stating, "... it is inferred that *Leopecten* may have descended from *Amussiopecten* before the Early Pliocene, but no intermediate form is known between the two."

Euvola (*Euvola*) differs from *Euvola* (*Leopecten*) in having a deeply convex right valve and a nearly flat to concave left valve, i.e., a pectinoid adaptive form. Early members of *Euvola* s.s. have either non-costate auricles or weak adventitious costae similar to those present on many *E.* (*Leopecten*); later members have two or three prominent costae on the dorsal regions of the left auricles. The earliest known *Euvola*, *sensu stricto*, is an unnamed species that occurs in the Baitoa Formation of the Dominican Republic in an age range that probably extends from late Burdigalian to Serravallian (Saunders et al. 1986: 37). This is possibly of about the same age as the oldest known occurrence of *Leopecten gatunensis gatunensis* in the lower member of the Alhajuela Formation of Panama (Woodring 1982: 584), thus indicating that the split between mildly right-convex *Euvola* (*Leopecten*) and deeply right convex *Euvola* (*Euvola*) had already occurred early in the history of this genus.

The new phylogenetic treatment of the *Decatopecten* group compared to that in Waller (1991) stems from new studies of the fossil history of this group. The tribe Decatopectinini Waller, 1986, as originally defined consisted of ten genera, all but one of which have distributions that are entirely or mainly in the tropical Indo-Pacific region. The exception is *Flexopecten*, which presently lives in the Mediterranean and adjacent eastern Atlantic with a single outlier species occurring in the western South Atlantic (Waller 1991: 36). In the original diagnosis of the Decatopectinini, four characters were used to define the group: (a) unusually fine and closely spaced regular commarginal lamellae, with a spacing density ranging from 30 to 70 lamellae per two-millimetre distance along a radius in center of disk at a distance of 10 mm from the beak; (b) very low inflation of the left beak, only slightly greater than that of the right beak; (c) antimarginal microsculpture very fine and restricted to early ontogeny of disk up to a point just distal to the origins of radial plicae; and (d) hinge dentition of the right valve dominated by dorsal and/or intermediate teeth, the latter sometimes multiple or absent, and resilial teeth low or absent.

Although *Flexopecten* is consistent with placement in the Decatopectinini in terms of characters (a) through (c), the extant species *Flexopecten glaber* (Linnaeus, 1758) and *F. flexuosus* (Poli, 1795) and their fossil counterparts in the European Pliocene and Pleistocene differ from other members of the tribe in hinge dentition. In *Flexopecten*, dorsal teeth are generally very weak, and resilial teeth are dominant, showing an out-turning and merger with the prominent ventral shelf of the hinge plate. Articulation is mainly the result of the resilial teeth of the right valve fitting into resilial sockets on the left and infradorsal teeth of the right valve resting in shallow infradorsal sockets on the left. Similar features are present in the closely related genus *Lissopecten*. This pattern is

more like that in the *Aequipecten* group than that in the *Decatopecten* group. Furthermore, the left beak sculpture of *Flexopecten* is commonly pitted, unlike that of other Decatopectinini where the left beak is smooth. Collectively these features indicate that *Flexopecten* should be removed from the Decatopectinini and placed in the *Aequipecten* group. This would imply that the dense, closely spaced commarginal lamellae of *Flexopecten* developed independently of this feature in the Decatopectinini. If the genus *Antipekten* Cossmann and Peyrot, 1914, of the European Miocene (Burdigalian-Serravallian) is ancestral to *Flexopecten*, as indicated by Roger (1939: 69, 91), then convergent development of dense commarginal lamellae seems likely, because *Antipekten* has far-set rather than close-set lamellae. I found looped commarginal lamellae on steep rib flanks in the early ontogeny of the specimen of *Antipekten pseudopandorae* (Berkeley Cotter 1904) from the lower Burdigalian of Portugal figured by Roger (1939, pl. 5, fig. 7), suggesting descent from within the *Aequipecten* group.

Another of the ten genera originally included in the Decatopectinini may also have a different phylogenetic origin from other members of the tribe. All extant species of *Annachlamys* Iredale, 1939, begin ontogeny after the prismatic stage with close-set commarginal lamellae, although their spacing is somewhat greater than the lower density limit given for the Decatopectinini by Waller (1986: 30 lamellae per two-millimetres measured 10 mm from origin of growth). At a point in ontogeny that varies among species, the dense commarginal lamellae give way to far-set, projecting lamellae. The transition is similar in all species, with the far-set condition arising first on the rib crests because of the merger or termination of some lamellae as they pass from rib interspaces onto rib flanks. This stage is then followed by loss of close-set lamellae in the rib interspaces as well. These later, far-set projecting lamellae crossing both ribs and interspaces resemble closely the lamellae present in the *Pecten perplanus* stock. *Annachlamys reeve* (Adams and Reeve, 1850) develops a single lira on each rib crest at a stage in ontogeny just before the end of the close-set lamellae, and this lira then continues into the far-set stage before terminating. The resulting transient growth stage is remarkably similar to the unilirate sculpture of the *Pecten perplanus* stock. A similar sculptural ontogeny occurs in *Annachlamys iredalei* (Powell 1958). In contrast, the other Decatopectinini genera display persistent close-set lamellae throughout ontogeny, and the earliest lamellae are more closely spaced.

The fossil record of *Annachlamys* appears to be limited to the Neogene (Miocene to Pleistocene) of the Indo-Pacific region. Examples are *Annachlamys okinawaensis* Noda, 1991, from the Ryukyu Islands, southwest Japan, *Pecten (Chlamys) suvaensis* Mansfield, 1926, and *Pecten (Chlamys) nausorensis* Ladd, 1934 from the late Miocene or early Pliocene of the Fiji Islands, and *Pecten murrayanus* Tate, 1886, from the Morgan Limestone of South Australia. The last species is possibly the oldest known *Annachlamys*. According to Ludbrook (1973: table 1) the Morgan Limestone contains planktic foraminiferal zones N7 and N8. According to Berggren et al. (1995) these are of late Burdigalian and Langhian age. Roger (1939: 16) noted that the extant species *Pecten leopardus*, which is now assigned to *Annachlamys*, is known from the Miocene of Java and that it is probably a living representative of his *Chlamys rotundata* group, a group that is closely allied to *Gigantopecten* (see Bongrain 1988). Indeed, some *Annachlamys* have

an unusual ontogenetic shift in convexity of the left valve, with the proximal part flattened, recalling the more extreme expression of this condition in the *Gigantopecten* clade.

Removal of *Flexopecten* and *Annachlamys* from the tribe Decatopectinini leaves eight genera in the tribe: *Anguipecten* Dall, Bartsch, and Rehder, 1938; *Bractechlamys* Iredale, 1939; *Decatopecten* Rüppel in Sowerby, 1839; *Excellichlamys* Iredale, 1939; *Gloripallium* Iredale, 1939; *Juxtamysium* Iredale, 1939; *Mirapecten* Dall, Bartsch, and Rehder, 1938; and *Somalipecten* Waller, 1986. All of these have tropical Indo-Pacific distributions at present, and there are few unequivocal fossil records older than the Miocene. There is but one comparable genus in older rocks, *Anatipecten* Hertlein, 1936, based on a type species, *Pecten anatipes* Morton, 1833, from the Oligocene of Alabama (Glauwe 1974: 8). It resembles *Decatopecten* in having a low number of broad plicae and very dense, closely spaced commarginal lamellae, but it differs in lacking well-developed intermediate hinge teeth and in having only very weakly developed internal rib carinae. The oldest species assigned to *Anatipecten* is *Chlamys (Lyropecten) incertae* Tucker-Rowland, 1938, which is common in the upper part of the Crystal River Formation of Florida (Nicol et al. 1989) of probable latest Eocene (latest Priabonian) age. To judge from figures of this species in Nicol et al. 1989: pl. 1), internal rib carinae are present at least in smaller individuals and intermediate hinge teeth are also present. This species, unlike *Annachlamys*, lacks sculptural features that would suggest a relationship to the *Pecten perplanus* stock, but the presence of internal rib carinae would suggest derivation from an aequiptectinine ancestor.

1.2.4 Eastern Atlantic *Pecten*

As reviewed above, molecular genetic studies of Atlantic *Pecten maximus* and Mediterranean *Pecten jacobaeus* have produced conflicting results. Either the genetic difference is so small that it may not be significant at the species level, or, where the geographic ranges of these species are in contact along an oceanographic barrier in the western Mediterranean, “there is a major discontinuity in interpopulation allozyme variation” (Ríos et al. 2002: 237). Comments on morphological similarity made in connection with some of the genetic studies have also been conflicting. Canapa et al. (2000b) indicated that the very close genetic similarity between *Pecten maximus* and *Pecten jacobaeus* is corroborated by their strong morphological similarity and evidence of morphological intergradation. As evidence for morphological intergradation, they claimed that there is “a variety with intermediate features, classified as *P. intermedius* by Monterosato in 1878, which is found off the coast of Portugal (near Gibraltar) and everywhere the ranges overlap.” Ríos et al. (2002: 223), in contrast, claimed that the major genetic discontinuity that separates populations on either side of Almería-Oran Oceanographic Front is “coincident in space with the morphological discontinuity between the two taxa.”

As far as I am able to determine from the literature, solid evidence for morphological intergradation of these species has never been presented. *Pecten intermedius* Monterosato, 1899 (not 1878), mentioned by Canapa et al. (2000b), is not recognised today as a valid species. It was based on specimens of *Pecten jacobaeus* from the

northern Adriatic, an area that today harbours populations of *P. jacobaeus* that are dense enough for commercial exploitation (Wilding et al. 1999). Purported zones of intergradation between *P. maximus* and *P. jacobaeus* along the southern Portugal coast mentioned by Canapa et al. (2000b) and along the Atlantic coast of northwest Africa have not been adequately documented and may not exist. In their extensive monographs of Neogene pectinids of Europe, Depéret and Roman (1902: 59, 97) did not report intergradation between these species, although they reported fossil *P. maximus* in Pleistocene terrace deposits in Atlantic Morocco to the south of Safi (about 32°N) and typical *P. jacobaeus* from Cádiz, on the Atlantic coast of Spain. Roger (1939: 246) reported that *P. maximus* or *maximus-jacobaeus* transitional forms occur rarely in Pleistocene deposits in Italy where *P. jacobaeus* is abundant. Although there were deep penetrations of *P. maximus* into the Mediterranean during cold periods of the Pleistocene (Raffi 1986; Malatesta and Zarlenga 1986), more detailed studies have failed to document any intergradation between these species. For example, Imbesi (1956), in a study of variations of *P. maximus* and *P. jacobaeus* from Pleistocene deposits in Sicily and Calabria, Italy, concluded that “although the two species show variability, no intermediate form exists.”

There is, however, evidence for morphological separation. Along the Algerian coast, Pallary (1900: 377) found *Pecten maximus* both to the west and east of Oran, including specimens as well developed as those in the Atlantic, and was able to distinguish these from *P. jacobaeus* living in the same area. Apparently recognising morphological differences in the spat of the two species, Cano et al. (1989) reported settlement of *Pecten maximus* but not *P. jacobaeus* on spat collectors at Málaga, Spain, west of the oceanographic front. Rombouts (1991) and Wagner (1991) both described generalised morphological differences between the species, and Ríos et al. (2002: 229) were able to use these differences to corroborate their allozyme study of populations on either side of the oceanographic front in the western Mediterranean.

In the present study, examination of museum collections of *Pecten jacobaeus* and *P. maximus* failed to turn up evidence for intermediate forms in the critical areas of the western Algerian coast, southwestern Spain, and southern Portugal. Comparison of 75 valves of *P. jacobaeus* and about 100 valves of *P. maximus* from throughout their geographic ranges indicate that shells as small as 20 mm in height are clearly distinguishable. In right valves of *P. jacobaeus*, radial costellae begin to develop atop plicae within a range of shell heights of 11–23 mm, most commonly appearing in heights of 11–19 mm. In contrast, on right valves of *P. maximus*, radial costellae atop plicae begin to form in a range of heights from 26 to 47 mm, mostly commonly in the range of 32–41 mm. Left valves differ more in the prominence of secondary costae atop plicae than in the timing of appearance. In late ontogeny, the left plicae of *P. jacobaeus* have rounded crests with secondary costae so weak that they are hardly discernible. In later ontogeny of the left valve of *P. maximus*, three to five well-developed radial costae appear. There is a greater difference in the presence and timing of appearance of secondary costae in the rib interspaces of right valves. In *P. jacobaeus*, these rib interspaces are non-costate (with a single exception, where costae appear very late in the ontogeny of a gerontic individual). In *P. maximus*, costellae begin to develop in the rib interspaces only a few millimetres later than do the costellae on the rib crests, and the interspace costellae attain the same amplitude and spacing as those on the rib crests.

Given the differences between these two species, the apparent lack of intermediate forms, their separate geographic ranges, and their long separation in the fossil record, it would seem premature to state that the very close genetic similarity indicated by partial sequences of the 16S rRNA gene indicates that they are parts of a single species. The same gene should be sequenced and compared in other species of *Pecten* that are morphologically more distant, such as *Pecten keppelianus* of the Canary and Cape Verd Islands and *Pecten sulcicostatus* G.B. Sowerby II, 1842, of southwester Africa, as well as Indo-Pacific *Pecten* species (see Waller 1991: 39).

1.3 CONCLUSIONS

New research on the morphology of fossil scallops of the family Pectinidae, particularly those from the early Cenozoic, has led to new phylogenetic hypotheses that are encapsulated in Figures 1.1–1.3. The new phylogenies indicate that extant pectinid genera comprise four subfamilies: Camptonectinae, Chlamydiae, Palliolineae, and Pectininae. Three of the four are monophyletic, the exception being the subfamily Chlamydiae, which is paraphyletic in the sense that it has provided the roots for the other three subfamilies. The Camptonectinae, represented by the extant genus *Delectopecten*, is the oldest of the monophyletic subfamilies, having branched from a chlamydinine ancestor before the end of the Triassic, approximately 220 million years ago. Next oldest is the Palliolineae, with an origination in the mid-Cretaceous (Albian), about 100 million years ago. The Pectininae is the youngest monophyletic group, traceable to an aequipectinine subgroup of the Chlamydiae in the late Middle Eocene, about 40 million years ago.

One of the major results of the present study is a new phylogeny of the Palliolineae, demonstrating the importance of this group in Cenozoic pectinid evolution in both hemispheres. It is subdivided into five tribes, all but one of which are monophyletic: Adamussiini, Mesopeplini, Palliolini, Pseudentoliini, and Serripectinini. The exception is the tribe Palliolini, which is paraphyletic in the sense that it is the group from which the Mesopeplini, a Southern Hemisphere group, originated.

The stem genus of the Palliolineae, *Dhondtichlamys*, originated from a chlamydinine ancestor in the Cretaceous (Albian) and is traceable into the Paleocene and Lower Eocene. Diversification of the Palliolineae occurred in two major pulses (Fig. 1.2), one in the Paleocene and Early to Middle Eocene during a time of global warmth, the other in the latest Eocene and Early Oligocene, during a time of global cooling and readjustment of oceanic circulation (Flower and Kennett 1994; Zachos et al. 1994; Thomas et al. 2000). The warm-phase clades contain the longest ranging genera of the subfamily: (a) the European *Pseudentolium-Korobkovia* lineage, which lasted for about 51 million years, from the Early Eocene (Ypresian) to the Late Pliocene; (b) the New Zealand-Australian genus *Lentipecten* (shown here to be distinct from European *Pseudentolium*), which survived for about 40 million years, from the Middle Eocene (Lutetian) to the end of the Miocene; and (c) the New Zealand-Australian genus *Serripecten*, which persisted for about 46 million years, from the Early Eocene (Ypresian) into the Late Miocene (Tortonian). These long-ranging taxa may well have been eurythermal and may have

achieved their longevity by being able to adapt to changing marine climate. Although the fossil record for the Eocene is not good enough to provide extensive distributional data, it is likely that these long-ranging genera were also geographically widespread. Two of the three clades that became restricted to the Southern Hemisphere, the Adamussiini and Serripectinini, originated during the warm phase of diversification.

Cooling-phase diversification during the latest Eocene through Early Oligocene (Rupelian, Chattian) includes the origin of the antarctic genus *Adamussium* from the long-ranging, probably eurythermal Southern Hemisphere genus *Lentipecten*. In the Northern Hemisphere, rapid diversification in the tribe Pallioliini occurred in northern basins of Europe, leading to the extant northern Atlantic genera *Placopecten*, *Karnekampia*, and *Pseudamussium*, and to the Southern Hemisphere extant genus *Mesopeplum*. *Mesopeplum* is the stem as well as the only survivor of a monophyletic clade of genera that evolved in the Southern Hemisphere, mainly in New Zealand (Beu and Maxwell 1990; Beu 1995) during the Miocene and Pliocene (Fig. 1.3). The extinct derivative genera are *Mesopeplum* (*Borehamia*), *Phialopecten*, *Kaparachlamys*, and *Towaipecten*, all of which occur in an interval of time from the Late Miocene through the Pliocene.

The third clade to survive the end-Cretaceous mass extinction is the paraphyletic subfamily Chlamydinae. Its evolution was discussed in Waller (1991, 1993), where it was shown that the tribe Mimachlamydini developed during the late Paleocene or early Eocene two incipient morphological characters indicating that it is the root for the Aequipectinini - a pitted microsculpture in the pre-radial stage of the left beak and internal rib carinae. New information on hinge dentition and trends of commarginal lamellae in Eocene and Oligocene pectinids indicates that the subfamily Pectininae, here redefined to include the tribes Pectini, Decatopectinini, and Amusiini, is rooted in the Aequipectinini, not in the Pallioliinae contrary to Waller (1991).

Study of a stratigraphic succession of Pectininae in the Oligocene and Miocene of Central America reconfirms the phylogenetic independence of the American genus *Euvola* and the European-Indo-Pacific genus *Pecten*. *Euvola* is ultimately rooted in the widespread Oligocene-Miocene genus *Amussiopecten* and so also is *Amusium*. Collectively these three genera comprise the tribe Amusiini. In contrast, true *Pecten* as well as the extant genus *Annachlamys* are both derived, but at different times, from the Upper Eocene to Pliocene genus *Gigantopecten*, the basal member of which is the Upper Eocene-Lower Oligocene European species "*Pecten*" *arcuatus*. These three genera, *Pecten*, *Annachlamys*, and *Gigantopecten* comprise the tribe Pectinini. The tribe Decatopectinini of Waller (1986) is here reduced to eight genera with the removal of *Flexopecten*, assigned to the tribe Aequipectinini, and *Annachlamys*, assigned to the Pectinini. Thus restricted, the Decatopectinini is a sister group of the Pectinini + Amusiini.

These phylogenetic refinements based on morphology and the fossil record create substantial reconciliation with the results of molecular genetic analyses compared to the earlier phylogenies of Waller (1991). To return to the questions posed in the introduction, the important points are as follows:

a) Molecular studies have thus far been unable to resolve satisfactorily whether *Placopecten* or *Chlamys* branched off first in pectinid phylogeny. Although there is still

lingering uncertainty because of the lack of suitable transitional fossils in the Miocene of northeastern North America, the present study reconfirms placement of *Placopecten* in the Palliolineae, meaning that it was a separate branch before the *Chlamys* group gave rise to *Aequipecten* and *Pecten*.

b) The molecular genetic results that have placed true *Pecten* close to the aequipectinine genera *Argopecten* and *Cryptopecten* are corroborated by the present study, which derives *Pecten* ultimately from an aequipectinine lineage.

c) The COI gene analysis of Matsumoto and Hayami (2000) that indicates a close relationship of *Flexopecten* and *Aequipecten* is also corroborated by the present study, in which *Flexopecten* is moved from the Decatopectinini to the Aequipectinini.

d) Molecular genetic studies that indicate that the extant species *Pecten jacobaeus* and *P. maximus* of the eastern North Atlantic and Mediterranean may actually be conspecific are not supported by the morphological study of specimens from present-day contact zones of these species or by studies of their fossil records. Reports of transitional forms may be spurious.

Thus far molecular genetic analyses have examined species distributed among 21 pectinid genera, but important gaps still remain for the testing of morphological phylogenies. These are *Delectopecten*, representing a very early branch of the Pectinidae, and the extant genera of the Palliolineae other than *Placopecten*, viz., the northeastern Atlantic genera *Palliolum*, *Karnekampia*, and *Pseudamussium*. Finally, the New Zealand-Australian genus *Mesopeplum* should be examined in order to verify its position within the Palliolineae.

ACKNOWLEDGMENTS

I thank Warren Blow, Barbara Bedette and Mary Parrish of the Smithsonian Institution for research assistance and artwork. Annie Dhondt, Koninklijk Belgisch Instituut voor Natuurwetenschappen, Brussels, Belgium, and David Jablonski, University of Chicago, provided useful information. This study has benefitted greatly from generous loans of European Cenozoic pectinids from the Département de Sciences de la Terre, Université Claude-Bernard, Villeurbanne, France, facilitated by Abel Prieur, and of New Zealand Cenozoic pectinids from the New Zealand Geological Survey, facilitated by Alan Beu.

AUTHOR'S ADDRESS

Thomas R. Waller - Department of Paleobiology, National Museum of Natural History, Smithsonian Institution, P. O. Box 37012, NHB MRC-121, Washington, D.C. 20013-7012, USA (E-mail: waller.thomas@nmnh.si.edu)

APPENDIX

Note 1.

Dhondtichlamys Waller, 2001, is a replacement name for *Microchlamys* Sobetski, 1977. The latter name is a junior primary homonym of *Microchlamys* Cockerell, 1911, a rhizopodan protozoan (Waller 2001).

Note 2.

An explanation of the usage of the name "*Eburneopecten*" *frontalis* for a species occurring in the Paleocene and Lower Eocene of Virginia and Maryland is necessary because of errors in the literature. The name *Pecten rogersi* Clark, 1895, was given by Clark to a species from the Paleocene Aquia Formation of Virginia. Dall (1898, April), recognising that Clark's name is a junior homonym (non *Pecten rogersi* Conrad, 1834), renamed Clark's species *Pecten frontalis* and expanded the concept of the species to include younger material from the lower Jackson group of Mississippi (Moody's Branch Formation, early Bartonian in age; Palmer and Brann 1965: 135). Seven months later,

Clark (1898, November), apparently unaware of Dall's action, introduced another new name, *Pecten dalli*, for the same species. Clark and Martin (1901, caption for Pl. 44, fig. 7) designated a type specimen for *P. rogersi* Clark from the Aquia Formation at Potomac Creek, Virginia (now USNM 207171), and recognised that the species extends into the lower Eocene Nanjemoy Formation of Maryland and Virginia. Dall in Schuchert (1905: 487), apparently overlooking the fact that a type had already been designated, incorrectly referred to specimens of *Pecten* (*Pseudamussium*) *frontalis* from the later Eocene at Garlands Creek, Clark County, Mississippi, as "cotypes", believing that these specimens are conspecific with the older specimens from Maryland and Virginia. The International Code of Zoological Nomenclature, however, clearly mandates (ICZN 4th Edition, Article 72.7) that a new replacement name has the same type(s) as the original name. Furthermore, specimens in the Smithsonian collections identified by Dall as "*Pecten frontalis*" from Mississippi are within the range of variation of *Eburneopecten scintillatus* (Conrad, 1865) from the same locality and are not the same as "*Eburneopecten*" *frontalis* from Virginia and Maryland. Palmer and Brann (1965: 135) incorrectly accepted Dall's "cotypes" as valid types and therefore chose to limit application of Dall's name to Upper Eocene specimens from Mississippi. They further suggested that the name *Pecten dalli* Clark, 1898, in the combination *Eburneopecten dalli*, should be reinstated, even though it is an objective junior synonym of *P. frontalis*, and should be used for the Virginia and Maryland species. This is clearly not in accord with the ICZN code.

Note 3.

Ward (1992: 66) determined that *Placopecten princepoides* (Emmons, 1858) is a senior synonym of *P. clintonius rappahanockensis* (Mansfield, 1936).

Note 4.

The name *Gigantopecten* Rovereto, 1899, is used herein as a full genus rather than as a subgenus of *Pecten* as was done by Bongrain (1988). There is perhaps no other group of pectinids for which a genus-group name is more contentious. In recent years, there has been a nearly even split among taxonomists as to whether the name of this taxon should be *Gigantopecten* or *Macrochlamis* Sacco, 1897a. Some authors regard the name *Macrochlamis* to be a misspelling of *Macrochlamys*, the suffix of the latter reflecting the correct spelling of the name *Chlamys*. In fact Sacco (1897b) himself corrected the spelling of *Macrochlamis* to *Macrochlamys* three months later in the same year in a monograph, of which the earlier paper was only a summary. If an automatic emendation of *Macrochlamis* to *Macrochlamys* is allowed, then the name *Macrochlamys* Sacco, 1897, falls because it is a junior primary homonym of *Macrochlamys* Benson, 1832, a gastropod. It was for that reason that Rovereto (1899) introduced *Gigantopecten* as a new name. Even here, however, the matter does not end, depending on how many other genera are regarded as synonyms of this genus. If the list includes *Oopecten* Sacco, 1897, as in Hertlein (1969: N358), then this name has priority over *Gigantopecten*.

Chapter 2

Development, Physiology, Behaviour and Ecology of Scallop Larvae

Simon M. Cragg

2.1 INTRODUCTION

There is a range of larval types in the Bivalvia, with the veliger larva being characteristic for the subclasses Pteriomorphia and Heterodonta (Zardus and Martel 2002). Veliger larvae have a remarkably well-developed anatomy with shared features of shell, velum, musculature, gut, nervous system and, in the pediveliger stage, foot (Cragg 1996; Morse and Zardus 1997). This probably reflects not just homology, but also the fact that during their planktonic life, veliger larvae are exposed to the same selection pressures – those relating to planktonic life in the euphotic zone. Scallop larval anatomy fits the normal bivalve pattern, but certain features may be used to distinguish scallops from other bivalves, or from each other.

This chapter presents information on larvae of the Superfamily Pectinoidea, but virtually all information relates to the Pectinidae, particularly the shallow water commercially-exploited species. Nonetheless, there is value in investigating non-commercial, often small scallops in this era of molecular biology in which the genetic potential of the whole family or superfamily may be exploited.

The chapter is a substantial revision of the review of Cragg and Crisp (1991) with about two fifths of the references cited being new, often updating and sometimes replacing sources cited in that review. Some of the areas covered have had an explosion of new information due to advances in techniques. For example, field and mesocosm studies have offered fresh perspectives on larval distribution and behaviour. Also, fluorescence microscopy techniques have provided a new understanding of the larval nervous system. Experimental investigation of sensory function, until recently not feasible on such small organisms, is yielding insights into settlement behaviour. Advances in larval biochemistry relate particularly to lipid metabolism and to the role of neurotransmitters and neuromodulators, especially in metamorphosis control. Larval rearing techniques have been refined with much attention being paid to bacteria as sources of disease and as protection against disease.

2.2 SCALLOP LIFE HISTORY CHARACTERISTICS

Studies of scallop development have focused on species with commercial potential from shallow temperate to tropical waters, which, with one exception, show typical

planktotrophic development. Species with smaller adults and from deeper waters have received less attention: evidence suggests that lecithotrophic development is more common in such cases. Direct development from egg to juvenile has not been reported in the Pectinidae, but does occur in the related Propeamussidae. In cases where direct study of development is difficult, evidence from egg and shell dimensions can be used to provide evidence of mode of development. Table 2.1 summarises the information available on these key dimensions.

The eggs of most species listed in Table 2.1 range from 60 to 85 μm in diameter, thus falling within the range characteristic for planktotrophic species in the Mytilidae (Ockelmann 1965). Mackie (1983) stated that bivalves with planktotrophic development generally have eggs with a diameter of less than 85 μm , while the eggs of those with lecithotrophic development range in size from 90–140 μm . Zardus and Martel (2002) confirmed the planktotrophic range, but revised the range for lecithotrophic development for non-protobranch bivalves to 90–300 μm . Eggs in the predicted lecithotrophic range have been reported from the scallops *Equichlamys bifrons* – a continental shelf species, *Bathypecten vulcani* – a hydrothermal vent species and *Pseudohinnites levii* – an abyssal species. Larvae of *E. bifrons* provided with a microalgal diet were reared to metamorphosis by Dix (1976), but whether these larvae ingested the algae is not stated.

Mytilid species with larger eggs also have larger prodissococonch I shells (Ockelmann 1965) and parental stocks of *Mercenaria* producing larger eggs give rise to larger prodissococonch I shells (Goodsell and Eversole 1992). Egg size data for lecithotrophic scallops is limited, but *Equichlamys* and *Pseudohinnites*, follow the pattern of larger shells from larger eggs (Table 2.1). In planktotrophic scallop larvae, there is a weak negative correlation between egg size and prodissococonch II size at metamorphosis, but no clear trend between egg size and prodissococonch I size (Fig. 2.1). Stocks of *Pecten maximus* that produce larger eggs, in some cases produce larger prodissococonch I shells (Paulet et al. 1988) and in other cases do not (Cochard and Devauchelle 1993).

Planktotrophic larvae have a much larger prodissococonch II (PII) than PI, while there is little larval shell growth after formation of PI in lecithotrophic species. Berkman et al. (1991) report a PI/PII ratio in planktotrophic larvae of 0.25 to 0.4 and of 0.6 or greater in lecithotrophic larvae. (To facilitate comparisons with the literature, the PI/PII ratio is used here, but it would perhaps provide a clearer insight into the difference between lecithotrophic and planktotrophic shells if data was presented in the form of percent growth from PI to PII.) Ratios in Table 2.1 range from 0.24 to 0.98 with two groupings: known or likely planktotrophic species ranging from 0.24 to 0.55; known or likely lecithotrophic species ranging from 0.87 to 0.98. A single specimen of *Crassodoma pusio* with a ratio of 0.63 falls between these. In addition to these species, there are a number of species reported by Schein (1989) and Kase and Hayami (1992) (though full data are not available) as having shells characteristic of non-feeding larvae (*Bathypecten eucymatus*, *Chlamydeila* spp., *Cyclopecten* spp., *Hyalopecten frigidus*, *H. undatus*, *Parvamussium* spp., *Propeamussium centobi* and *Swiftopecten swifti*) or of planktotrophic larvae (*Chlamys bruei*).

Footnotes

1. Egg diameter indicated; prodissococonch I (PI) shell width parallel to hinge; prodissococonch II (PII) shell width at metamorphosis; PI/PII is ratio of the two shell widths.
2. Where two dimensions are divided with a slash, figures relate to different parental stocks.
3. Asterisk denotes dimensions estimated from published micrographs.
4. Shape: image of shell profile provided if marked +; presence of hinge teeth noted if marked +; numbers of anterior and posterior teeth with range.
5. Identification tentative.

Figure 2.1. Relationship between egg diameter, and width of prodissococonch I and II shells in pectinid larvae with planktotrophic development.

By using evidence from egg size and larval shell ratios we can conclude that almost all shallow water scallop species have planktotrophic development, whether in the Antarctic (*Adamussium*), temperate waters (e.g., *Pecten*) or tropical waters (e.g., *Bractechlamys*) and at least two bathyal to abyssal species have this mode of development. Lecithotrophic development occurs in a single temperate water species (*Equichlamys*), several sublittoral cave-dwelling species (Kase and Hayami 1992), many bathyal and abyssal species (Schein 1989; Dijkstra and Knudsen 1997; Le Pennec and Beninger 2000), a hydrothermal vent species (*Bathypecten vulcani*) and species of *Caribachlamys* from coral reefs (Waller 1993). A further indication of the lecithotrophic, low dispersal mode of development for *Bathypecten* is the observation that larvae of a species of this genus only settle close to known parental stocks (Mullineaux et al. 1998). Gregarious settlement is reported in *Leptopecten* (Morton 1994), though whether this is due to having lecithotrophic larvae with limited dispersal capability, or to settlement cues from congeners remains to be established. Planktotrophy is the dominant development mode in euphotic waters, but where suspended particulate food is limited (e.g., in shallow

caves and in the abyss) or where the parental environment is extremely patchy (coral reefs, mid-ocean ridges), lecithotrophy may improve the chances of survival to settlement in the parental environment. Lecithotrophic development may also correlate with small adult size (Kase and Hayami 1992, Schein 1989).

Ockelmann (1965) stated that there were no records of direct development or brood protection for any deep sea pectinids, the reviews of bivalve development by Sastry (1979) and Krasyanov et al. (1998) report none for pectinids in any environment and none have come to light during the preparation of this chapter. Brooded larvae lack a PII, and PI is often unusually shaped and textured (Berkmann et al. 1991). The propeamussiids examined by Hayami and Kase (1993) lacked a PII and in *Chlamydella incubata* and *C. tenuissima* the PI has radiating or diagonal ribs, and the shape is like a conical, broad-brimmed hat. These species were found to brood a few (commonly 3–7) embryos and to retain the juveniles in the suprabranchial chamber, attached by their byssus to the maternal gill. Mode of development in the genus is variable, however, as they point out that *C. favus* from lower neritic substrata off southern Australia has a smaller, normal-shaped PI and so is unlikely to be brooded. *Propeamussium imbriferum* and *P. groenlandicum* are also reported to be brooders (Wada 1953 in Kasyanov et al. 1998).

With their vast numbers of small eggs released per spawning and prolonged period of larval dispersal, the planktotrophic species appear to be *r*-strategists. Even a species which is mature at just over 10mm length and is thus less fecund and may not be planktotrophic shows characteristics of an *r*-strategist (Morton 1994). The small cave-dwelling propeamussiids, particularly the brooding species, are *K*-strategists adapted for a stable low-productivity environment (Hayami and Kase 1993).

The timing of stages of larval development varies considerably from species to species, though information on early stages is sparse (Table 2.2). In addition to the putative constraints of food supply, depth and patchiness of adult environment, temperature also affects scallop life history characteristics.

Cell division during the cleavage stages is distinctly faster at 20°C than at 15 or 10°C (Zavarzina 1981). For a given species, time to metamorphosis varies with temperature across the physiologically tolerated temperature range: at 18°C, *Pecten maximus* larvae reached metamorphosis in 35 days, but at 15°C, 44 days were required and at 12°C, 51 days. At 9°C, only a small proportion of larvae metamorphosed after 65 days (Beaumont and Barnes 1992). Sublethal low temperatures arrest veliger growth and subsequent development when temperature rises to optimal temperatures is retarded (Beaumont and Budd 1982). Data from the planktotrophic pectinids on temperature and time to metamorphosis fits to an Arrhenius plot (Fig. 2.2) that also fits the data for individual species across the temperature range at which they can achieve metamorphosis. This suggests that the energy of activation of a critical step required for development to metamorphosis is remarkably constant within the family.

Size at metamorphosis of planktotrophic species shows a trend of decreasing size with increase in temperature evident particularly in data from laboratory rearing of species at close to their temperature optimum (Fig. 2.3). A negative correlation of this sort also occurs in other bivalve families (Lutz and Jablonski 1978). Data from field collections of larvae generally lack sufficient information about temperatures during larval

Table 2.2

Figure 2.2. Arrhenius plot with units converted to days and degrees C of relationship between water temperature and time from fertilisation to metamorphosis for planktotrophic (●) and lecithotrophic (○) larvae. Sources are listed in Tables 2.1 and 2.3.

development to permit detailed analysis of this correlation. However, measurements from recently settled spat of eight pectinids at 20, 50 and 70 m depth by Peña et al. (1998) suggest that the correlation probably occurs under field conditions. The average PII width was 200 μm for species settling only at 20 m (*Flexopecten* spp.), was between 217 and 257 μm for species settling over the whole range (*Mimachlamys*, *Aequipecten*, and *Pecten* spp.) and was 291 μm for those that settled only at 70 m (*Pseudamussium*). The deeper settling species may well have experienced a colder temperature regime during larval development. The PII size/temperature trend of planktotrophic species may relate to the same development/temperature interaction that is manifest in the negative correlations between a) water temperature and length of the larval stage and b) egg size and size at metamorphosis.

Figure 2.3. Relationship between water temperature and size at metamorphosis of planktotrophic and lecithotrophic larvae of pectinids. The regression line relates to the planktotrophic data. Abyssal and bathyal species have been assigned a very approximate water temperature of 3°C to permit display and comparison.

The data for lecithotrophic species is insufficient to investigate the relationships between temperature and PII size or time to metamorphosis. However, it seems likely that given the shorter developmental period for lecithotrophic species, size and time to metamorphosis is mainly regulated by egg reserves, which may in turn be directly affected by environmental constraints or by limitations imposed by adult size.

2.3 LARVAL DEVELOPMENT

2.3.1 Embryogenesis

In the Pectinidae, gametes are released into the sea and fertilisation occurs externally. Sperm penetration takes place while the egg is at the metaphase I stage of meiosis. Fertilisation and early cleavage stages have been investigated in detail in *Pecten* and *Placopecten* (Gruffydd and Beaumont 1970; Désilets et al. 1995). Temperature, salinity and pH all affect the timing of the stages of meiosis (Desrosiers et al. 1996). Subsequent cell divisions have been investigated in a number of species (Table 2.2). Cell lineages

have been traced up to the 16-cell stage. Division is spiral, complete and heteroquadrantal; further cell divisions lead to the formation of a stereoblastula (Tanaka 1984; Malakhov and Medvedeva 1986); this blastula type is typical of bivalves with yolk-rich eggs (Sastry 1979). The blastula is not motile (Kulikova and Tabunkov 1974). A gastrula is then formed by epiboly and invagination (Gutsell 1930; Fullerton 1890; Drew 1906; Hodgson and Burke 1988).

The roughly spherical gastrula develops to form a trochophore larva. The end of the larva that leads as it swims - the apical end or pretrochal region - is rounded and surmounted with a tuft of long cilia. The other end of the larva is tapered with indentations on either side of the larva, corresponding to the shell gland and the archenteron (Gruffydd and Beaumont 1972; Malakhov and Medvedeva 1986; Hodgson and Burke 1988; Belolio et al. 1993).

2.3.2 Development of the Larval Shell

A surface infolding, the shell field invagination, develops on the dorsal surface of the trochophore. Within this is the shell gland (Fullerton 1890; Sastry 1965; Malakhov and Medvedeva 1986; Bellolio et al. 1993; Casse et al. 1998). This structure with its wide transverse opening consists of cells derived from blastomeres Xs and Xd (Malakhov and Medvedeva 1986). Cells with numerous yolk granules bear microvilli that line the gland and some of which partially close off the opening (Casse et al. 1998).

A thin pellicle elaborates across the opening, which allows the organic matrix of the shell to be deposited (Casse et al. 1998). Initially, a continuous sheet consisting of two discs joined by a bridge of the same material is formed (see Hodgson and Burke 1988 and Figs. 2.4 and 2.5), which together partially envelop the post-trochal region. Prodissoconch I shell secretion is initiated at the end of the trochophore stage after the gland everts (Malakhov and Medvedeva 1986, Casse et al. 1998). Casse et al. (1998) provide diagrams that show how identified cells are repositioned during eversion to form the edge of the mantle with its periostracal groove.

The appearance in SEM specimens of the pellicle and pre-prodissoconch I structure, suggests that it is thinner and less rigid than the larval shell in later stages (compare Figs. 2.4 and 2.7; see also Casse et al. 1998). Humphreys (1969) suggests that this material is the precursor of the periostracum and it is likely that there is initially little or no calcification, as is the case of *Tridacna squamosa* (LaBarbera 1974). In pectinids, the outer surface of the shell takes on a less flimsy appearance due to calcification within less than a day: the central region of the shell valves becomes covered with small pits and is surrounded by a rim which has no pits but is marked with radial striations (Lucas and Le Pennec 1976; Hodgson and Burke 1988; Bellolio et al. 1993; Casse et al. 1998; Fig. 2.6). This pattern of surface sculpture described by Carriker and Palmer as "punctate-stellate" also occurs in oyster larvae (Carriker and Palmer 1979; Waller 1981), but in oysters, the pitted (punctate) region is rather smaller.

Figure 2.4. 42-hour larva of *Pecten maximus* viewed from opposite end to apical pole. Scale bar = 10 μ m. **h** = developing hinge, **mo** = mouth, **te** = telotroch, **s** = non-calcified shell.

Figure 2.5. Detail of specimen in Fig. 2.4. Scale bar = 10 μ m.

Figure 2.6. 50-hour D veliger of *Pecten maximus*. Shell (**s**) showing punctate stellate sculpturing of pits and radial striations. Non-retractable velum (**v**) with central apical flagellum (**af**). Scale bar = 10 μ m.

Figure 2.7. Umboned veliger of *Pecten maximus*, showing concentric growth lines on the shell, the prodissoconch I/prodissoconch II boundary (**arrowheads**). Compound preoral cirri form a band (**b**) around the rim of the velum (**v**) and the apical tuft (**t**) protrudes from the centre of the velum. Scale bar = 10 μ m.

The bridge between the two discs of the shell quickly develops into a straight-edged hinge. The discs become the shell valves and these take on the D-shaped outline characteristic of the prodissoconch I shell of early bivalve veligers (see Fig. 2.6 and Table 2.1). This shell consists of a single homogenous layer of vertical crystallites (Salaün 1994 in Casse et al. 1998)

A distinct change in shell growth occurs shortly after the formation of the D-shaped valves. Further shell-growth takes place at the margins of the prodissoconch I shell. This, the prodissoconch II, can be distinguished from the prodissoconch I by its concentric growth rings (Bellolio et al. 1993; Fig. 2.7). In *Placopecten* veligers there are major and minor growth rings correlating closely with the number of days growth after initiation of secretion of the prodissoconch II shell (Hurley et al. 1987). Ring deposition occurs at the same rate in constant conditions including constant illumination. Thus the possibility of an innate rhythm of secretion, perhaps on a tidal rather than daily cycle, such as that described in an adult bivalve, by Richardson et al. (1980) should be considered. However, Salaün and Le Pennec (1992) sought, but did not find any such correlation in their studies of *Pecten* veligers.

The punctate region of the prodissoconch I is secreted by the shell gland whereas the remainder of the shell is secreted by the rim of the mantle. The concentric growth rings appear once the larva becomes capable of closing the shell (Cragg 1985; Bellolio et al. 1993) and may be due to fluctuations in shell secretion caused by shell closure (Waller 1981). The larval hinge-line differentiates during the secretion of the prodissoconch II shell (Le Pennec 1980, Bellolio et al. 1994). At either end of the hinge there is a line of roughly rectangular teeth with matching depressions in the hinge of the opposite shell valve. These teeth resemble those on the hinges of adult taxodont bivalves. The middle part of the hinge-line is devoid of teeth: the ligament is located near the centre of this area (Zakhvatkina 1959; Waller 1976; Le Pennec 1980; Barichivith and Stefoni 1980; Kulikova et al. 1981; Tanaka 1984; Hodgson and Burke 1988). It is presumably due to the ligament that empty larval shell valves tend to gape and this provides the antagonistic mechanism opposing the adductor muscles (Cragg 1985). As the larva grows, the straight hinge line is gradually obscured by the developing umbos, though these never become as pronounced as in larvae of the other families of bivalves (Rees 1950; Chanley and Andrews 1971).

Scanning electron microscopy has proved particularly valuable in elucidating the disposition and number of the components of the hinge (Table 2.1). Changes in hinge morphology during development have been studied in various pectinids (Maru 1972; Le Pennec 1974 and 1980; Tremblay et al. 1987; Bellolio et al. 1994). Four-day-old *Placopecten magellanicus* veligers have no hinge teeth, but by seven days, six teeth are present; in later stages, up to ten and possibly more are present (Tremblay et al. 1987). D-veligers of *Patinopecten yessoensis* have only two teeth per shell valve at each end of the hinge line, rising to six by the end of the pediveliger stage (Maru 1972). In *Pecten ponticus*, *P. maximus*, *Chlamys hastata* and *Argopecten purpuratus* the number of hinge teeth also increase during larval development (Zakhvatkina 1959; Le Pennec 1974; Hodgson and Burke 1988; Bellolio et al. 1993), though no such increase is evident before

metamorphosis in the micrographs of *Chlamys varia* (Le Pennec 1980). The amplitude of the teeth increases during larval development (Waller 1976; Bellolio et al. 1994).

The end of planktonic life is marked by a further distinct change in shell secretion. Shell continues to be added at the margin of the valves, but this juvenile (dissoconch) shell has a different appearance (Gruffydd and Beaumont 1972; Maru 1972; Le Pennec 1974; Dix 1976; Hodgson and Burke 1988; Waller 1991; Bellolio et al. 1993). This clearly marked boundary permits the estimation from spat of the size of pediveligers at metamorphosis (Jørgensen 1946; Merrill 1961). The difference in appearance reflects the chemical nature of the two shell types: the dissoconch has a higher calcium salt content and lower organic content than prodissoconch II (Merrill 1961), though the larval shell is sufficiently calcified to warrant decalcification before sectioning with glass knives for electron microscopy (Hodgson and Burke 1988; Cragg 1989). The boundary between prodissoconch II and the dissoconch is also a boundary between two crystalline forms of calcium carbonate: aragonite in prodissoconch II and calcite in the dissoconch (Waller 1976; Fatton and Bongrain 1980; Waller 1991). The dissoconch of pectinids is composed of two layers, the inner of which is formed of foliated calcite. The outer layer of the right valve is composed of prismatic calcite and that of the left is formed of a material that gives a pitted appearance to its surface (Fatton and Bongrain 1980 and authors reviewed therein; Bongrain and Fatton 1982).

Following metamorphosis, the hinge-line becomes straight again and the “wings” which are characteristic features of the hinge of adult scallops appear (Merrill 1961; Sastry 1965; Le Pennec 1974 and 1980). After reaching their maximum amplitude at metamorphosis, the larval hinge teeth slowly disappear (Le Pennec 1974; Hodgson and Burke 1988). The ligament grows along the dorsal edge of the ears and forms resilium in a deep triangular pit below the umbo (Le Pennec 1980; Bellolio et al. 1993).

2.3.3 Organogenesis

2.3.3.1 Development of ciliation, the prototroch and the velum

Apart from shell secretion, changes in the distribution of cilia on the larva are the most significant external evidence of the changes taking place during early larval development. Authors describing a number of pectinid species (see Table 2.3) are agreed that the first stage to possess cilia is the gastrula and that by the trochophore stage, the larva has a conspicuous apical flagellum composed of long cilia. They are less unanimous about the distribution of other cilia apart from the apical flagellum. The diagrams of Sastry (1965) and Costello et al. (1973) indicate that the remaining cilia of the trochophore are evenly distributed over the whole larva, whereas those of Drew (1906), Belding (1910) and Gutsell (1930) suggest that these cilia are restricted to the area extending from the apical tuft to the invagination of the shell gland. Malakhov and Medvedeva (1986) show these cilia only around the equatorial region of the larva. These observations used light microscopy with which, in such transparent organisms, it is difficult to determine the distribution of cilia. Using scanning electron microscopy, Hodgson and Burke (1988) found that in *Chlamys hastata* the ciliation of the gastrula is

restricted to two groups of two to four primary trochoblasts on the perimeter of the blastopore and a further two groups of primary trochoblasts girdling the embryo. By the trochophore stage, the prototroch has developed from these primary trochoblasts and consists of a ring of cells bearing a band of sparsely distributed single cilia extending around the equator of the larva (the apical flagellum being situated at the anterior pole).

At the posterior pole, there is a small tuft or ring of cilia, the telotroch. SEM studies of *Pecten maximus* and *Argopecten purpuratus* larvae have revealed a similar prototroch (Cragg 1989, Bellolio et al. 1993) and, in the early shelled larva, a group of cilia posterior to the mouth (see Fig. 2.4), which may be homologous to the telotroch of Hodgson and Burke.

The most characteristic organ of bivalve veligers is the velum, which emerges as a distinct organ during the transition from trochophore to veliger. The pretrochal region, which is domed in the trochophore, becomes flattened, forming the roof of the velum: the prototroch becomes dilated, forming its rim. Initially the velum is an almost solid group of cells (Sastry 1965; Gruffydd and Beaumont 1972; Malakhov and Medvedeva 1986) which cannot be retracted, but the body cavity soon extends into the velum and the larva becomes capable of rapidly withdrawing the velum within the shell valves (Cragg 1985). For illustrations of the velum, see authors listed in Table 2.3. The roof of the velum is devoid of cilia apart from the centrally located apical flagellum (Fig. 2.6) or in later larvae, apical tuft (Hodgson and Burke 1988; Cragg 1989 and Figs. 2.7 and 2.8).

The rim of the velum, on the other hand, is profusely ciliated, with five bands or rings of cilia extending right around the rim (Hodgson and Burke 1988; Cragg 1989; Bellolio et al. 1993, Fig. 2.8). Closest to the roof of the velum is the inner preoral ring consisting of single cilia, below this are two rings of markedly longer cilia grouped into cirri, each composed of more than one row of cilia aligned at right angles to the rings. The arrangement of these cilia is best seen in the bases remaining in a deciliated velum (Bellolio et al. 1993). Below the preoral cirri is a tract of shorter single cilia - the adoral tract, and then a ring of postoral single cilia. The naming of the rings of cilia relates to their position relative to the mouth as the larva moves through the water. The mouth itself is located at the posterior end of the velum: it consists of an opening in the adoral tract with an associated tuft of cilia or compound cilia.

Viewed from above, the velum has a roughly oval outline, though with slight indentations on either side (Hodgson and Burke 1988) so that Culliney (1974) describes it as keyhole shaped and Cragg (1989) as pear-shaped. In *Chlamys hastata*, the preoral cirri appear to be borne on a ridge running around the rim of the velum, as are the postoral cirri, with the adoral tract running in a shallow gutter between the two ridges. The velum of *Pecten maximus* may have a similar topography (see Fig. 4 of Cragg 1989). When the velum retracts, it folds with a longitudinal furrow (Cragg 1985; Hodgson and Burke 1988). Apart from the region of the apical tuft, the roof of the velum consists of an extremely thin epithelium; so does the epithelium joining the velum to the mantle folds. The cells of the velum rim, on the other hand, are much larger, particularly those bearing the preoral cilia, which have numerous large mitochondria and an extensive ciliary rootlet system (Cragg 1989). Hodgson and Burke (1988) report the presence of secretory cells on the rim of the velum, among the cilia-bearing cells.

Figure 2.8. Disposition of cilia on the velum of veliger of *Pecten maximus* (from Cragg 1989 with minor modifications). A: lateral view of veliger in typical swimming attitude with swimming direction indicated by arrow. For the sake of clarity, only the cilia on anterior and posterior end of velum are shown. Solid line indicates plane of section shown in B, outlined area shown in C. B: Transverse section of veliger. Outlined area shown in D. C: Disposition of bases of cilia on the rim of the velum. a: inner preoral ring; b1, b2: upper and lower rings of preoral cirri; c: adoral tract; d: postoral ring. Arrows indicate direction of power stroke. D: Section of rim of velum. Note that upper and lower rows of preoral cirri are both shown, but as they are out of register, so they would not both appear in a true section.

2.3.3.2 Larval mantle

The inner surface of each shell valve is lined with an epithelium which turns back at the rim, forming two folds, then joins the epithelium of the velum or the foot or, at the anterior or posterior regions close to the hinge, forms a bridge between the valves. The epithelium is generally rather thin, being composed of cells that are much less tall from apical to basal surface than they are wide. Where it lines the shell, the apical surface lies directly against the shell: where it extends between the shell valves, it has a brush border of short microvilli at the apical (outward-facing) surface. The basal surface of the epithelium rests on a thin basal membrane. The cells of the folds are more columnar in character, with some much larger than the rest. A layer of periostracum curves back on itself to overlie the outer mantle fold and extends into the groove between the two folds. The cytology of the mantle folds of *Pecten maximus* is summarised in Fig. 2.9. The inner mantle fold bears cilia (Sastry 1965; Bellolio et al. 1993) which are grouped into a variety of formations described below in the section dealing with putative sense organs (section 2.3.3.5).

2.3.3.3 Musculature

No functional muscles are present in the trochophore, but rapid differentiation during the period of secretion of prodissoconch I results in the appearance in the early veliger of velar retractor muscles and the anterior adductor (Fullarton 1890; Sastry 1965; Maru 1972; Cragg 1985; Malakhov and Medvedeva 1986; Meyer and Bourne 1990; Bellolio et al. 1993). During development, the number of velar retractors increases and retractor muscles attach to the posterior body wall (Cragg 1985; Malakhov and Medvedeva 1986; Bellolio et al. 1993). The posterior adductor develops by the late veliger or pediveliger stage (Jørgensen 1946; Sastry 1965; Maru 1972; Tanaka 1984; Cragg 1985; Bellolio et al. 1993).

The foot of the pediveliger also has retractor muscles (Cragg 1985) perhaps developed from some of the retractors of the posterior body wall.

All retractor muscles are composed of striated muscle, but both anterior and posterior adductors have smooth and striated components. A strip of smooth muscle extends from the digestive mass and probably attaches at the rim of the shell. Smooth muscle fibres are also found near the mantle folds (Fig. 2.9) and associated with the gut (Cragg 1985). In *Pecten maximus*, the velar retractor muscles are attached to the shell near the hinge-line and branch profusely before attaching to the velum. They form a pattern that is symmetrical about the plane between the shell valves (Figs. 2.10 and 2.11). The pattern may vary in its details, but it has certain features that are constant for a given species. The posterior adductor consists of a single column, but the anterior adductor consists of two columns (Fig. 2.12), one of striated muscle and one of smooth muscle (Cragg 1985; Bellolio et al. 1993). The figures of Jørgensen (1946) suggest that *P. septemradiatus* and *Chlamys striata*, may also have a two-part anterior adductor, but that *Chlamys opercularis* does not.

Figure 2.9. Section of mantle perpendicular to the ventral rim of the shell of a veliger of *Pecten maximus*. Location of detail shown in B is outlined in A. Plane of section similar to that in Fig. 2.5D. Labels: ci - cilium, co - companion cell for nerve, gb - Golgi body, lv - electron lucent vesicles, m - mitochondrion, m1, m2, m3 - types of microvilli, mu - smooth muscle, ne - nerve profiles, rer - rough endoplasmic reticulum, s - shell, sr - striated rootlet, v - velum, 2 - type 2 ciliated mantle cell.

Figure 2.10. The major muscles of the veliger of *Pecten maximus* viewed from the left-hand side with smooth muscle indicated by spots and striated muscle by dashes (Cragg 1985). Only the left hand set of retractor muscles are shown. Labels: *d* – smooth muscle, *dm* – digestive mass (stomach plus digestive gland), *h* – hinge, *i* – intestine, *m* – mouth, *p1-p3* – posterior retractors, *sm* – smooth adductor, *st* – striated adductor, *1-4* – velar retractor muscles.

Where muscle is connected to the shell (Fig. 2.13), it attaches by means of modified mantle cells, whose structure of fibrils and hemidesmosomes resembles that of cells at muscle insertions on the larval shell of the oyster, *Crassostrea virginica* (Elston 1980) and of a nudibranch, *Phestilla sibogae* (Bonar 1978): where muscle attaches to the velum, there is no intervening cell layer and the structure of the point of attachment is less complex (unpublished obs.).

Figure 2.14. Apical flagellum of 42-h larva of *Pecten maximus*. Scale bar 2 μ m.

2.3.3.4 Digestive tract

In addition to the shell gland mentioned above, the scallop trochophore has another invagination, the archenteron with its opening, the blastopore (Drew 1906; Belding 1910; Malakhov and Medvedeva 1986; Hodgson and Burke, 1988). The digestive tract develops from this, becoming open at both ends in the early veliger stage.

Development of the morphology of the tract from early veliger to post metamorphosis has been investigated in most detail in *Patinopecten yessoensis* (Bower and Meyer 1990). The mouth is situated at the posterior end of the velum, opening into a straight ciliated cylindrical oesophagus with actively beating cilia (Beaumont et al. 1987), which leads to the stomach. The stomach itself is ciliated and food can be seen rotating inside live larvae. A crystalline style with a style sac is present at the posterior end of the stomach (Sastry 1965; Tanaka 1984; Bower and Meyer 1990). A pair of digestive diverticulae opens off the stomach.

A thin intestine is initially straight but develops one then two loops (Bower and Meyer 1990, Figs. 2.10 and 2.11) leads to the anus which is located close to the hinge line in the posterior body wall, dorsal to the posterior adductor in pediveliger larvae. Light microscope studies indicate the presence of labial palps adjacent to the mouth in older veligers or pediveligers (Belding 1910; Jørgensen 1946; Sastry 1965; Maru 1972), but these have not been reported in SEM studies (Hodgson and Burke 1988; Cragg 1989; Bellolio et al. 1993). The diagrams showing the palps depict contracted larvae, whereas the SEM studies show expanded larvae. Further investigation is required to establish the location and nature of the palps, and their mode of development.

2.3.3.5 Sense organs

Scallop larvae develop a range of putative sense organs during larval life. First to appear is the so-called apical flagellum, which appears at the apex of the pretroral region of the trochophore and is lost within a day or two of the development of the shell. In its place (now the centre of the velum) there remains a short apical tuft. During the veliger stage, a variety of ciliated tufts appear on the rim of the mantle. At about the time that the umbones become apparent, the veliger develops a pair of pigmented eye spots. By the pediveliger stage, a pair of statocysts has developed near the base of the foot.

2.3.3.6 Apical organ

The apical "flagellum" is in fact a group of long cilia adhering to one another to form a whip-like structure (Bellolio et al. 1993; Fig. 2.14). The apical tuft, which is found in the centre of the velum after the disappearance of the apical flagellum is composed of cilia which do not adhere together and which are situated in a shallow circular depression (Hodgson and Burke 1988; Fig. 2.15), which appears as a pit in contracted larvae (Bower and Meyer 1990).

The following description of the apical region in *Pecten maximus* is based on observations using preparation methods detailed in Cragg and Nott (1977) and Cragg

(1989). The apical flagellum generally protrudes stiffly from the larva with its tip bent back during swimming by the flow of water, but in some larvae it twitches intermittently and in one early veliger, it was seen to vibrate rapidly with small amplitude movements. It consists of up to 50 cilia with the normal $9 + 2$ microtubule arrangement, which may be as much as $100\text{ }\mu\text{m}$ long (Figs. 2.6 and 2.14). It arises from a single cell (as was also reported in *Argopecten irradians* by Belding 1910). The rootlets of the cilia extend to the base of the cell. These rootlets are cross-striated by major bands and more numerous sub-bands with a striation pattern periodicity of approximately 50 nm (Fig. 2.16). The cirrus-bearing cell has a basally located nucleus, a Golgi body and, in the apical cytoplasm, numerous mitochondria that are larger than those of neighbouring cells. It also contains a number of spheroidal osmophilic granules resembling those found throughout the trochophore and early veliger, some as large as the nucleus. It is likely that these granules are the lipid droplets that act as the energy store for early larval stages (Whyte et al. 1987). The brush border of this cell is similar to that of neighbouring cells. The apical flagellum is lost at about the time the veliger becomes capable of closing the shell valves. Other ciliated cells appear adjacent to the cirrus cell, which they resemble but for the nature of their cilia (Fig. 2.17). These cilia lack striated rootlets and are shorter. They are obliquely rather than perpendicularly oriented to the free cell surface, or are associated with depressions in that surface, or are partly enveloped within the apical cytoplasm. Small cells appear at the base of the apical cirrus cell and its neighbours.

Further differentiation in the central region of the velum results in the formation of an apical organ directly overlying the connective between the two lobes of a cerebral ganglion. A similar arrangement is reported in *Patinopecten yessoensis* (Bower and Meyer 1990). The apical organ consists of a disc-shaped region of thickened epithelium formed from cell types not found elsewhere in the velum. It bears a number of short cilia and, in extended, fixed larvae, it lies in a depression at the apex of a volcano-like prominence in the centre of the velum (Figs. 2.7 and 2.15). A similarly shaped apical organ occurs in veligers of *Chlamys hastata* (Hodgson and Burke 1988). The shape of this region in live larvae has not been reported.

Much of the free surface of the apical organ is formed by cells bearing a particularly well-developed brush border (Fig. 2.18). The long microvilli of these cells rarely branch. In between the microvilli are layers of extracellular material resembling that observed in the brush border of the rim of the velum (Cragg 1989), but with a more extensive amorphous layer (Fig. 2.19). In the apical cytoplasm of these microvillus cells, there are membrane-bound osmophilic granules and electron-lucent vacuoles, and a compact Golgi body may be found. The nucleus is basally located. The cells bearing the cilia forming the tuft of the apical organ are rather elongated: nuclei belonging to them are found towards the base of the apical organ epithelium. They bear up to ten $9 + 2$ type cilia attached to perpendicular striated rootlets (whose striation periodicity is about 50 nm) with associated horizontal rootlets which appear to stretch from cilium to cilium (Fig. 2.20). Horizontal microvilli arise from the free surface of these cells and interweave between the vertical microvilli of the brush border (Fig. 2.21). The cytoplasm of these cells contains elongated mitochondria and rough endoplasmic reticulum. Occasionally, dense cored vesicles $60\text{--}80\text{ nm}$ in diameter resembling those within the neuropil of the

A pigmented cup (pc) with osmophilic granules surrounds the core. Similar granules occur in the nearby mantle epithelium. Scale bar = 1 μm .

cerebral ganglion are found within these cells. The cytology of these cells resembles that of the apical cirrus cell from which they may be derived.

The third major component of the apical organ epithelium are irregularly-shaped cells with cilia projecting into an intracellular cavity (Fig. 2.22). These cells generally lie within the epithelium, but some have a small portion of the apical cytoplasm projecting between the other cell types to the free surface of the apical organ. Occasional examples with the cavity opening to this surface have been found (Fig. 2.23). No more than 15 cilia have been found in a single cell. The cilia lack striated roots (Fig. 2.24), but have the normal $9 + 2$ configuration with side arms on the microtubules (Fig. 2.25). They extend into the cavity from more than one direction (Fig. 2.25). Intracellular axonemes have occasionally been found in these cells in pediveliger larvae. The cytoplasm of these cells contains multivesicular bodies, a Golgi body and dense-cored vesicles approximately 70 nm in diameter. The nucleus is generally located below the cavity. The basal portion of the cell lies close to the commissure between the two lobes of the cerebral ganglion with no intervening basement membrane. However, no extensions from these cells have been found in the neuropil and no synapses have been found in the epithelium.

2.3.3.7 Statocysts

Statocysts formed by invagination (Moor 1983) have been reported from several larval pectinids listed in Table 2.3. In *Pecten maximus*, the invagination of the epithelium of the foot remains, forming a spherical sac connected to the mantle cavity by a cylindrical ciliated canal (Cragg and Nott 1977). Openings to these canals have also been observed in *Argopecten purpuratus* (Bellolio et al. 1993). The cilia of the canal are directed inward. Specialised ciliated cells - hair cells - form the majority of the wall of the sac. The bases of the cilia belonging to one cell are arranged in a circle or a circular array, with basal feet pointing inwards and horizontal striated roots probably radiating outward. Several statoconia (dense non-cellular bodies) of varying shape, size and structure are found free in the lumen of the sac. These can be seen in jerky motion in live larvae. Similar bodies occur within a single non-ciliated cell in the wall of the sac. A small nerve stretches from the pleural ganglion along the wall of the statocyst canal towards the sac of the statocyst. Its fibres may connect with thin processes extending from the hair cells (Cragg and Nott 1977).

2.3.3.8 Eye spots

A pair of eye spots have been observed in older veligers and pediveligers of many pectinids (Table 2.3). Eye spots can be seen through the transparent shell, appearing roughly in the centre of the valve when the larva is viewed from the side. The actual location of the eye is (in *Chlamys hastata*) on the anterior aspect of the gill bar; it consists of one cell with pigmented granules forming an anteriorly directed cup and another cell within the cup (Hodgson and Burke 1988; Fig. 2.26). Eye spots are developed by larvae of the Pteriomorphia and Heterodonta (Cragg 1996) and appear to be retained in adults of some Arcoida and Pterioda (Morton 2001).

2.3.3.9 Mantle ciliation

A study of critical-point-dried specimens broken open to remove obscuring tissues (using the methods described by Cragg 1985) has shown that the inner mantle fold of *Pecten maximus* larvae, prior to metamorphosis, has five different sorts of groupings of cilia on it, referred to as types 1–5 in the following text (Figs. 2.9 and 2.27). At five days old, no groupings of cilia are evident on the inner mantle fold, but 13-day veliger larvae have type 2 groupings and type 1 groupings appear in umboned veligers. By the pediveliger stage, all five types of grouping are present.

As many as four type 1 groupings have been found on a valve, each with up to five short (less than 6 μm long) cilia protecting from a small circular depression (Fig. 2.28). Unlike cilia from some other grouping types, these cilia do not appear stiff in SEM specimens. These groupings are situated near the anterior margin of the shell. Six or less type 2 groupings (Fig. 2.29) were found in 13-day old larvae, but there were up to 13 of them in pediveliger specimens. They are each formed from a row of about 25 cilia (exceptionally as many as 70) arranged in a line. These cilia are comparatively long (up to 21 μm) and are generally straight in SEM specimens. In live retracted larvae, they can be seen beating with no metachronal pattern evident. Six or less type 3 groupings occur in an arc which runs around the posterior margin of the valve, but further from the rim of the valve than type 2 and 4 groupings. Type 3 groupings are stiff tufts of up to 14 cilia with a maximum length of about 9 μm (Fig. 2.30). The type 4 grouping is made up of a line of single cilia running around the posterior margin of the valve (Fig. 2.30). The type 5 grouping is found along the mid-line of the epithelial bridge which lies between the valves and dorsal of the anus. It consists of a row of about ten short (up to 8 μm) single cilia, each arising from a small hemispherical protruberance (Fig. 2.31).

Only type 2 and type 3 configurations have been identified in sections. Fig. 2.9 summarises what is known about the cytology of the cell-type bearing type 2 configurations. The cilia of such configurations arise from a single cell that is much longer than its neighbours. In SEM specimens, these cells can be distinguished not only by the line of cilia along their inner margin (i.e., the margin furthest from the shell rim), but also by their distinctive long unbranched microvilli. The basal part of these cells contains the nucleus and rough endoplasmic reticulum; the middle part is filled with a particularly large Golgi body; the apical cytoplasm is full of large electron-lucent vesicles. The cilia are attached to long striated rootlets. Simple nerves containing cell profiles, some with neurotransmitter-like vesicles (Fig. 2.32), have been observed in the mantle epithelium close to the type 2 cells, or in the space within the mantle folds (Fig. 2.9). These nerves generally have non-nerve companion cells closely associated with them. Croll et al. (1997) found cells in the mantle rim of *Placopecten* veligers, with fluorescence indicative of catecholamines, which can function as neurotransmitters.

The cells bearing the type 3 cilia have not been subjected to detailed study, but sections reveal that associated with these groupings there are one or two specialised cilia on the ventral side of the group, borne on a neighbouring cell which lacks microvilli. Such cilia have the normal 9 + 2 arrangement, but are surrounded by a corona of nine

Figure 2.27. Distribution of types of configuration of cilia on the inner mantle fold of the pediveliger. A: lateral view of left valve with soft tissues indicated by dotted line and shell by solid line. B, C, D: sections along the lines marked on A. Labels as for Figs 2.28–2.32 plus: aa – anterior adductor, f – foot, g – gill buds, mo – mouth.

microvilli that are wedge-shaped in cross section (Fig. 2.33). These microvilli project a small distance above the level of the microvilli of surrounding cells. Longitudinal fibrils extend from the microvilli into the apical cytoplasm. Extracellular filamentous material extends circumferentially from microvillus to microvillus, and radially from each microvillus to the cilium. Sections suggest that cilium and microvillar corona arise from a columnar extension from the surface of the cell which is otherwise devoid of cilia and microvilli. However, insufficient examples have been seen to determine whether this is always the case.

Patterns of cilia have also been found on the mantle fold of *Argopecten purpuratus* (Bellolio et al. 1993): groups of up to ten cilia emerging from protuberances and single cilia projecting from a circular depression. The groups and single cilia alternate around the rim. The groups appear similar to the type 3 cilia described above.

2.3.3.10 Foot

The appearance of a foot in the later stages of larval development in pectinids has been noted by many of the authors listed in Table 2.3. Hodgson and Burke (1988) found that in *Chlamys hastata* the foot rudiment appears after 15 days development and becomes functional after 34 days, only a few days before metamorphosis. The functional foot in this species (and in *Argopecten* - Bellolio et al. 1993) is a somewhat sock-shaped organ, which is profusely ciliated on its “sole” (ventral surface), but sparsely ciliated on its lateral and dorsal surfaces. Culliney (1975) noted the presence of long mobile cilia on the toe of the foot of *Placopecten magellanicus*. These may correspond to the long cilia borne by processes from cell bodies with catecholamine-associated fluorescence found in this region by Croll et al. (1997). These processes extend from 15 to 20 cells, which seem to be connected to the pedal ganglion.

A byssal duct opens at the “heel” and a byssal groove extends forward along the “sole” from this opening (Gruffydd et al. 1975; Hodgson and Burke 1988). The duct has a bilobed blind ending (*Pecten maximus* - Gruffydd et al. 1975) or consists of two ciliated canals (*Chlamys hastata* - Hodgson and Burke 1988).

Five gland types can be distinguished in the foot of the pediveliger of *Pecten maximus*, characterised by their staining with Azan and toluidine blue. Equivalents of four of these have been identified in juveniles of *Patinopecten yessoensis* (Bower and Meyer 1990). The secretions of these glands are likely to resemble similarly staining secretions in homologous glands in *Ostrea* and *Mytilus* that have been examined with cytochemical techniques (Gruffydd et al. 1975). The primary byssus gland (also recognised by Hodgson and Burke) surrounds the bilobed blind ending to the byssal duct: it probably secretes highly sulphated acid mucopolysaccharides. The pedal mucus glands extend to the tip and anterior end of the sole of the foot. The secondary byssus glands are situated near the opening of the byssus duct and may produce a collagenous secretion. Two types of phenolic gland discharge a secretion likely to be phenolic protein into the anterior end of the byssal groove.

The gills are another organ that appears during the later stages of larval development and is retained through metamorphosis. Gill development in *Pecten* is of the papillary type (Raven 1958), in which a row of papillae is formed on either side of the foot in a postero-anterior sequence (Beninger et al. 1994). In studies of live pectinid pediveligers, gills have been detected in a number of species (Table 2.3). The observations of *Chlamys hastata* and *Pecten maximus* pediveligers using SEM and histological sections (Hodgson and Burke 1988; Beninger et al. 1993) reveal more detail: on either side of the foot there is a ridge of tissue extending from the mantle into the mantle cavity which bears three to five small lobes - the primary gill filaments - formed from cuboidal epithelium containing large vacuoles filled with granules. Belding (1910) reports that in *Argopecten irradians* there are initially two gill filaments on either side of the foot, but by metamorphosis there are four or five occasionally contractile filaments bearing active cilia. On each filament of *C. hastata* there is a single row of simple cilia that beat inwards in anteriorly-directed metachronal waves.

2.3.3.11 Nervous system

The nervous system of the pediveliger of *Ostrea* and *Mytilus* consist of a bilobed cerebral ganglion joined by connectives to paired pleural, visceral and pedal ganglia (Erdmann 1934; Ranieri 1995). Nerves run from the larval eyes to the same connective and the nerve from the statocyst connects to the visceral ganglion (Erdmann 1934). Most components of this system have been recognised in light microscope and TEM sections of larvae of *Patinopecten yessoensis* (Bower and Meier 1990), *Chlamys hastata* (Hodgson and Burke 1988) and *Pecten maximus*. The bilobed cerebral ganglion is described in the section of this chapter that deals with the apical organ. The visceral ganglion has been identified (pers. obs.) and the relationship between the pedal ganglion, the pleural ganglia and the statocysts is illustrated by Cragg and Nott (1975).

Hatschek (1880) described a plexus of nerves radiating to the velum rim from the cerebral ganglion in *Teredo*, while Ranieri (1995) reported two rows of acetylcholinesterase-staining bipolar neurons at the base of the velum and connecting with the cerebral ganglion in *Mytilus*. Evidence for innervation of the velum has also been found in pectinids. Nerve profiles have been identified in TEM sections of the velum of

Pecten (Cragg 1989) and, in *Placopecten*, fluorescent staining for catecholamines has revealed nerve connections similar to those described by Raineri. Four to eight catecholamine-staining cell bodies have been revealed on the outer rim of the velum. These are connected around the rim by two to three fibres (Croll et al. 1997). No evidence of a radiating plexus was revealed by this approach, though a fibre connecting from a pair or more of flask-shaped, fluorescing cells on either side of the mouth was found to extend to the region of the cerebral ganglion. These cells may correspond to the nerve cell clusters with acetylcholinesterase activity near the oesophagus of *Mytilus* reported by Raineri (1995) and the catecholaminergic cells near the mouth of the prosobranch *Crepidula* (Dickinson et al. 1999). The position of these cells and their connections is suggestive of control of feeding mediated by the cerebral ganglion, perhaps in response to sensory information. Indeed, there is some evidence of nervous control of feeding: serotonin has been reported to inhibit the ciliary transport rate in the oesophagus of a nudibranch veliger (Pavlova et al. 1999).

Further studies combining aldehyde-induced fluorescence and immunofluorescence with confocal laser microscopy are needed to fully reveal the extent and nature of connections in the apical organ and velar nervous system. A more detailed examination of distribution of neurotransmitters or neuromodulators needs to be considered as studies of a range of gastropod larvae have revealed staining for the peptide FMRFamide and for serotonin in cells of the apical organ and in fibres extending from the apical organ to the velum (Kempf et al. 1997; Dickinson et al. 1999).

There are nerves, which have not been mentioned in other descriptions of bivalve larvae - those associated with retractor and adductor muscles, and with the inner mantle folds, though their connections to ganglia remain to be clarified (Cragg 1985; this chapter). Those connecting to the retractor muscles have a constant diameter, while those connecting to the adductor muscles have varicosities, as has also been observed in nerve processes in the velum (Croll et al. 1997).

2.3.3.12 Other organs

Anatomical and histological studies of veligers and pediveligers from other bivalve families (e.g., *Teredo* - Hatschek 1880; *Ostrea* - Erdmann 1934; *Crassostrea* - Galtsoff 1964; *Mytilus* - Bayne 1971) have revealed a few organs, which have either not been investigated in detail or not described at all from pectinid larvae. The larval heart or its precursor has been observed by Hatschek and Erdmann: it is functional in pediveligers of *Crassostrea virginica* (Galtsoff 1964). No equivalent of this has been reported from any pectinid larvae, nor is there any mention of the larval kidneys illustrated by Erdmann, Hatschek and Bayne.

2.3.4 Metamorphosis

Towards the end of larval life, pediveligers initiate settlement behaviour. This change is reversible – larvae can return to the previous behaviour patterns. However, at some stage during settlement, the irreversible morphogenetic changes involved in

metamorphosis may be triggered. In scallop larvae, as in other bivalve larvae, the process of metamorphosis involves changes in the nature of shell secretion, loss of some organs, greater development and/or relocation of others. The changes in shell shape and structure, which are described in a section above, must result from changes in the mantle, but no information is available regarding the modifications of mantle fold morphology and cytology. The principal organs lost at metamorphosis are the velum, the velar retractor muscles and the anterior adductor.

Accounts of the loss of the velum differ markedly: whether this indicates that the process of velum loss varies between pectinid species or that different interpretations are put on the process is unclear. Most accounts state that the velum is lost at the end of the pediveliger stage: Culliney (1975) reports that the velum of *Placopecten magellanicus* is cast off in large pieces or even as a single piece, while in *Chlamys hastata* it is histolysed (Hodgson and Burke 1988) and in *Pecten maximus* it degenerates (Gruffydd and Beaumont 1972). The account of Sastry (1965) of metamorphosis of *Argopecten irradians* suggests a remarkable degeneration of the velum almost complete by the time the foot is functional. However, Gutsell (1930) and Chanley and Andrews (1971) provide illustrations of pediveligers of *A. irradians* that show no sign of degeneration of the velum. The loss of the anterior adductor at metamorphosis has been reported by Belding (1910) and Sastry (1965), but diagrams of Jørgensen show it to be retained in recently settled spat of *Pecten septemradiatus* and *Chlamys opercularis*.

There is a general migration, relative to the axes of the shell, of those organs that survive metamorphosis (Belding 1910; Jørgensen 1946; Sastry 1965; Hodgson and Burke 1988). This results in the mouth moving from its postero-ventral larval location to the adult antero-dorsal position, the foot becoming ventral rather than posterior and the posterior adductor migrating to the centre of the valve (Belding 1910). Sastry's diagrams indicate that the migration of the mouth commences during the veliger stage, but the illustrations of Chanley and Andrews (1971) and Gutsell (1930) show no evidence of such migration, even in pediveligers.

After metamorphosis, the gill filaments increase in length and number (Belding 1910; Gutsell 1930; Sastry 1965; Hodgson and Burke 1988). The outer filaments of the adult gill system appear after metamorphosis (Belding 1910), the cilia of the larval gills become the lateral ciliated band and the frontal cilia appear (Hodgson and Burke 1988). The gill becomes capable of suspension feeding within a day of metamorphosis, ensuring that there is little ingestion loss during the transition (Gruffydd and Beaumont 1972).

The shape of the foot gradually changes after metamorphosis (Sastry 1965). The glands present in the pediveliger foot become better developed (Gruffydd et al. 1975) and the byssus secreted changes abruptly to a more sticky form after metamorphosis (Culliney 1975). In *Argopecten irradians* the heart and pericardium are first apparent in the light microscope in spat (Belding 1910), with beating first evident two weeks after metamorphosis (Sastry 1965), but Fullarton (1896) reports a heart in a pediveliger, which may have been *Chlamys opercularis*, taken from the plankton. Of the putative sense organs of the pediveliger, the statocysts are retained (Belding 1910; Sastry 1965); so are the eye spots (Gruffydd 1976) though these probably have no association with the adult eyes which appear in much later stages on the rim of the mantle.

The fate of the groupings of cilia on the inner mantle fold is not known. However, Belding (1910) reports the presence of cilia on the mantle of spat and the region where the cilia occur on the mantle probably represents the precursor of the adult inner mantle fold, which bears sensory tentacles. These first appear a few days after metamorphosis (Sastry 1965). The fate of the apical organ is uncertain: in a number of species of bivalves, cells of the apical organ participate in the formation of the labial palps (Cragg and Crisp 1991). Sastry's comments on the formation of palps suggest that this may also be the case in *Argopecten irradians*. As there appear to be either genuine differences in palp development between different pectinid species or differences of interpretation, the question of palp development deserves closer scrutiny.

2.4 COMPARATIVE ANATOMY

The general anatomical layout of pectinid veligers - bivalved shell, velum, musculature, digestive tract, nervous system, certain sense organs and foot - is typical for planktotrophic bivalve larvae. The mantle structure is probably also typical. Two mantle folds have been reported from the larvae of a number of other bivalve species (Cragg and Crisp 1991): only the remarkably large, teleplanic pediveliger of *Planktomya* has been reported to have the adult complement of three folds (Allen and Scheltema 1972).

In the venerid *Ruditapes*, the non-motile flagellum borne by three central cells is retained through larval life and is surrounded by sub-epithelial cells with ciliated cavities (Tardy and Dongard 1993). Some form of apical ciliation, either in the form of a flagellum formed from numerous cilia or a ciliary tuft, has been reported for veligers of other bivalve taxa (Zardus and Martel 2002). Indeed, apical structures bearing tufts of cilia occur in planktonic larvae in many phyla (Nielsen 1995). The embryological origin of apical organ of larvae from a wide range of spiralian phyla is sufficiently similar to suggest homology (Hadfield et al. 2000). Furthermore, serotonin immunoreactivity has been detected in the apical organ of polychaetes, brachiopods, phoronids, nudibranchs and echinoids (Kempf et al. 1997). Additionally, the arrangement of a sensory ciliated epithelium overlaying the commissure between the lobes of the cerebral ganglion is common to gastropod and bivalve veligers. Indeed, the ciliated cavity cells of the apical organ of *Pecten maximus* resemble the cells termed ampullary neurons in the apical organ of the veligers of prosobranch and nudibranch gastropods, and annelid trochophores (see studies and reviews of Page 2002; Kempf et al. 1997). Thus, evidence for homology of elements of the apical sensory structures in molluscs is strong (Hadfield et al. 2000).

The opposed-band arrangement of cilia on the velum may be homologous with similar features in larvae from other molluscan classes and from other protostomian phyla (Strathmann et al. 1972; Strathmann and Leise 1979; Nielsen 1995), though independent evolution of the opposed-band mechanism has also been proposed (Rouse 1999).

The velar retractor muscles are lost at metamorphosis as are similar muscles in many gastropods. The question as to whether these larval muscles represent a synapomorphy for the entire phylum Mollusca has been investigated by Wanninger and Haszprunar (2002a). Their conclusion is that, as no such larval muscles occur in the Polyplacophora, they are not an ancestral feature for the phylum, and their observations of a lack of special larval

muscles in scaphopods (Wanninger and Haszprunar 2002b) indicate that such retractor muscle systems rather than being an ancestral feature for the Conchifera (= Scaphopoda, Gastropoda, Bivalvia, Cephalopoda) could have evolved independently in the Gastropoda and Bivalvia.

The papillary mode of gill development occurs not only in pectinids, but also in *Arca*, *Anomia*, *Modiolus*, *Mytilus* and *Ostrea* of the Pteriomorphia and *Dreissena* of the Heterodonta (Raven 1958). Multiple statoconia have been found, not only in pectinid pediveligers, but also in other members of the Pteriomorphia: single statoconia on the other hand have been reported only from the Nuculoida, Veneroida and Myoida (Cragg and Nott 1977). A possible exception to this is the report of Stafford (1912) that veligers with single statoconia she had collected from the plankton could be identified as *Placopecten magellanicus*. However, Merrill (1961) doubted the precision of this identification and Stafford's illustrations do not resemble those of Culliney (1974), who reared larvae of this species. Indeed, the larvae illustrated differ sufficiently from the descriptions of the authors listed in Table 2.1 that it seems unlikely that they were pectinids. Gruffydd et al. (1975) found that there are homologues of certain of the pedal glands of *Pecten maximus* in two other members of the Pteriomorphia - *Mytilus edulis* and *Ostrea edulis*.

Tufts of cilia on the inner mantle fold, possibly of similar origin to those observed in *Pecten maximus*, have been reported in *Ostrea edulis* (Cranfield 1974; Waller 1981) and tufts of morphology and position similar to types 2 and 3 groupings of *P. maximus* were observed in another oyster, *Crassostrea gigas* (Cragg 1976). The cilia of the type 3 configurations with their corona of microvilli resemble structures on the mantle tentacles of *Placopecten magellanicus* adults (Moir 1977). They also resemble collar receptors found in organisms in several major taxa: gastropods (Crisp 1981), adult nuculid bivalves, turbellarians, (Haszprunar 1985) gastrotrichs (Teuchert 1976), kinorhynch plus other invertebrates (Nebelsick 1992) and cnidarians (Golz and Thurm 1993). Several phylogenetic interpretations of these possible homologies are considered by Haszprunar.

Illustrations of the shell of pectinid veligers and pediveligers (citations in Table 2.1; Fig. 2.34) show that once the shell loses the "D" shape, it takes on a characteristic outline with rather indistinct umbones and an anterior margin which is more tightly curved than the posterior margin. None of the other bivalve families surveyed by Chanley and Andrews (1971) have such an outline, though mytilids are somewhat similar (see Fuller and Lutz 1989). The taxodont teeth at either end of the hinge-line in pectinid veligers are also similar to those in anomids and mytilids, but unlike mytilids the region in between is devoid of teeth. The distribution and type of teeth distinguishes pectinid veligers from those of other bivalve families (Rees 1950; Le Pennec 1980). Lateral indentations to the outline of the velum (Culliney 1974; Hodgson and Burke 1988; Cragg 1989) may prove to be another characteristic feature of pectinids.

Features of the hinge, such as number of teeth, shape and position of ligament (Le Pennec 1980; Tanaka 1984), and of shell outline (Table 2.1, Fig. 2.34) may also permit species of pectinids to be distinguished from one another. Jørgensen (1946) noted species-specific shell pigmentation in larval pectinids. The pattern of retractor muscle distribution may also prove to be characteristic (Cragg 1985). Diagrams of Jørgensen

(1946) suggest that the degree of separation of the components of the anterior adductor and the pattern of coiling of the intestine varies from species to species. Further information relating to the features mentioned above would enable keys to pectinid larvae to be prepared.

Many descriptions of veligers list measurements of the dimensions of the shell and hinge line. Care should however be taken in using size data derived from laboratory-reared larvae as species-characteristic features, because Sasaki (1979) has shown that the size at metamorphosis can be affected by rearing conditions and the observations of Paulet et al. (1988) suggest that genetic factors may account for significant variation within a species of size at metamorphosis. Sasaki found that the mean width at metamorphosis of *Pecten maximus* was 247 μm in spat collected from the sea and 223 μm in hatchery-reared spat: the corresponding figures in *Chlamys opercularis* were 225 μm and 201 μm (the measurements for each species represent the means of 100 measurements of spat from the sea and of 60 spat from the hatchery). Paulet and his colleagues found that the mean size of metamorphosing larvae derived from one stock of *Pecten maximus* from a site in north western France differed significantly from those derived from another nearby stock with different spawning characteristics.

Figure 2.34. Outline of prodissococonch II shell in larval pectinids, with hinge above and anterior end to the left. A: *Pecten maximus*, scale bar 25 μm (Salaun and Le Pennec 1992); B: *Argopecten purpuratus*, scale bar 20 μm (Bellolio et al. 1994); C: *Bathypecten eucymatus*, scale bar 50 μm (Schein 1989); D: *Chlamys hastata*, scale bar 20 μm (Hodgson and Bourne 1988); E: *Equichlamys bifrons*, scale bar 50 μm (Dix 1976); F: *Adamussium holbecki*, scale bar 100 μm (Berkman et al. 1991).

2.5 FUNCTIONAL MORPHOLOGY

2.5.1 Locomotion

The trochophore moves by means of the simple, relatively short cilia of the prototroch. With the depletion of lipid reserves and the secretion of the shell, the larva becomes denser and requires a more effective means of propulsion. This is provided by an increase in the ciliated band circumference relative to body size due to the formation of the velum, and by the greater propulsive power of the long cirri of the main preoral ciliary bands. The cilia of the other bands on the velum are unlikely to contribute significantly to the propulsion of the larva. Though the main thrust of the preoral cirri tends to propel the larva velum first, the weight of the shell deflects the swimming path and a small tangential force generated either during the active beat or the recovery stroke probably accounts for the rotation of the larva as it swims. The density of the shell means that when the velum retracts, the direction of movement abruptly changes and the larva sinks more rapidly than it can swim (Cragg 1989).

The control of beating of the preoral cilia is probably due to a mechanism similar to that in gastropod veligers investigated by a number of authors reviewed by Arkett et al. (1987). Arkett and colleagues showed that in veligers of the gastropod *Calliostoma* the cells bearing the preoral cirri are connected by gap junctions and are thus electrically coupled. Propagated Ca^{++} -dependent action potentials are initiated from the cerebral ganglion, causing velum-wide arrests of ciliary beating, while reduction in beating rate is accompanied by a slow depolarisation of the cell membrane. Direct evidence of excitatory nervous control by sensory serotonergic cells in the probable homologue of the apical sense organ of marine gastropods has been obtained from laser ablation studies with pulmonate embryos (Kuang and Goldberg 2000). Experimentation has demonstrated that the velum of *Mytilus* larvae has dual innervation: excitatory serotonergic and inhibitory dopaminergic (Beiras and Widdows 1995). Acetylcholinesterase occurs in the ciliated cells of the velum in *Mytilus* (Raineri 1995). Immunofluorescence studies suggest nervous control of the ciliated cells with connected catecholaminergic cells on the rim of the velum, but no rim to apical organ connections yet located (Croll et al. 1997). The abrupt cessation of beating and changes in beating rate that occur in *Pecten maximus* veligers (Cragg 1989) suggest that nervous control similar to that revealed by Beiras and Widdows (1995) probably occurs in pectinids.

Precisely-ordered sequences of contraction of the various components of the musculature effects the body movements involved in velum contraction and protraction (Cragg 1985). In the pediveliger stage, crawling is accomplished by a combination of the creeping due to the cilia of the sole of the foot, followed by a sudden contraction of the foot presumably due to the pedal retractor muscles, which draw the shell towards the tip of the foot (Gruffydd et al. 1975 - *Pecten maximus*; Hodgson and Burke 1988 - *Chlamys hastata*). Mucus secreted by glands near the tip of the foot is likely to facilitate creeping, but no equivalents of the tip attachment glands of *Mytilus* and *Ostrea*, which probably temporarily anchor the tip of the foot during contractions, have been found in *Pecten*

maximus pediveligers. The remaining pedal glands secrete various components of the byssus, which permit the larva to temporarily anchor itself (Gruffydd et al. 1975).

2.5.2 Feeding

The ciliation of the velum plays an important role in feeding. The arrangement of bands of cilia is comparable with those of organisms that feed by the “opposed band” filtering mechanism. In this mechanism, studied in veligers of *Crassostrea gigas* by Strathmann and Leise (1979) and of *Mercenaria mercenaria* by Gallagher (1988), the long preoral cirri sweep particles such as algal cells towards the adoral tract. The postoral cilia may prevent particles from being swept further and the adoral tract carries the captured particles towards the mouth. Veligers can clear between 3.4 and 38.5 $\mu\text{L h}^{-1}$, when feeding in algal suspensions, with feeding rate increasing with increasing temperature (Lu and Blake 1997).

Bivalve larvae have been shown to be capable of taking up nutritionally-significant quantities of dissolved amino acids from seawater through the velum (Manahan and Crisp 1982) as can the gills of newly-metamorphosed spat of *Pecten maximus* (Manahan and Crisp 1983). Though the gills become the feeding organ in postlarvae, pediveliger gills are non-functional in this respect (Beninger et al. 1994). Gills become capable of filter-feeding a day after metamorphosis (Gruffydd and Beaumont 1972), so that the uptake of dissolved organic matter by the gills may help bridge the gap between the loss of velar filtering and the initiation of gill filtering (Manahan and Crisp 1983).

Particles captured by the velum enter the ciliated oesophagus. Le Pennec and Rangel-Davalos (1985) studied the fate of ingested unicellular algae in veligers of *Pecten maximus* using epifluorescence microscopy. The gut becomes functional shortly after shell secretion. At high densities of algal cells, ingestion and digestion are continuous and breakdown of ingested cells of readily digested algal species starts 5–6 hours after ingestion and is complete after 10–11 hours. Variations in ingestibility of similar-sized algae (Lora-Vilchis and Maeda-Martinez 1997) suggest a selective capability, perhaps at a ciliated sphincter at the junction between the mouth and the oesophagus (Gallagher 1988; Bower and Meyer 1990). The presence of catecholaminergic cells in this region, which have connections running to the apical organ (Croll et al. 1997), may be evidence of some form of nervous control of ingestion, with perhaps interaction through the apical organ to the swimming cirri. Field studies suggest that veligers of *Placopecten* are capable of selective feeding (Raby et al. 1997).

2.5.3 Respiration

The large surface-area-to-volume ratio of larvae, the currents generated by ciliary beating and the short internal diffusion distances mean that no separate respiratory organ is necessary of respiratory demands. No identified respiratory structures develop during the veliger stage and it is not certain whether the gills in the pediveliger function in gaseous exchange. The fluid of the body cavity is only separated from the surrounding seawater by the thin epithelia of the velum and mantle. The cells bearing the preoral cirri,

which are directly in contact with a stream of water generated by ciliary activity, probably constitute the site of highest oxygen demand as evidenced by their large and numerous mitochondria. The mantle cavity is separated from this current by the velum, so perhaps the beating of the type 2 cilia of the mantle serve to prevent water from stagnating in the cavity.

2.5.4 Sensory Reception

The structure of the apical organ suggests that it is a sense organ, but a sensory role has not been demonstrated experimentally. Its role is particularly unclear in the trochophore and early veliger where the nervous system has yet to differentiate. In later veligers, broad conclusions about function can be drawn on the basis of structural similarities with more thoroughly investigated organisms. The complex brush border of the apical organ, with vertical and horizontal microvilli interwoven with extracellular material, is similar to that of molluscan chemosensory epithelia on the osphradium (Crisp 1973), olfactory organ (Yi and Emery 1991) and tentacles (Wright 1974). The cells bearing the cilia forming the apical tuft resemble sensory neurones in such epithelia. The ciliated cavity cells of the apical organ resemble cells in a range of putative or known chemosensory structures: the apical sensory organ of nudibranch veligers (Chia and Koss 1984), the rhinophore of *Nautilus* (Barber and Wright 1969), the lip of *Sepia* (Emery 1975), the olfactory epithelium of *Octopus* (Woodhams and Messenger 1974) and the ampullary system of chitons (Haszprunar et al. 2002). The sensory modality of this cell type remains to be established in many cases, though Lucero et al. (1992) have detected an electrical response to chemical stimuli from similar cells in squid. Detailed studies with the probably homologous (see section 2.4) apical sensory organ of gastropod larvae are also illuminating. Cells that correspond in location, size and number to cells with ciliated cavities in the apical sensory organ of a nudibranch veliger have been demonstrated to be responsible for detection of chemical settlement cues (Hadfield et al. 2000). Receptors for similar cues have been located on cilia harvested from metamorphically competent veligers of a prosobranch (Baxter and Morse 1992), though in this investigation, the location of the organ providing the cilia was not known.

The type 1, 3, 4 and 5 configurations of cilia on the mantle all consist of groups of cilia too small and too few to create significant currents by beating, so the possibility that they are sense receptors should be considered. As the mantle ciliation reaches greatest complexity in pediveligers, the sensory role may relate to cues for settlement. The cilia from the type 3 groupings with corona of microvilli resemble structures found in known mechanoreceptors (see for example Moir 1977; Haszprunar 1985; Golz and Thurm 1993). The orientation of the basal structures of the cilia from the cells forming the sac of the statocyst resembles that of cells demonstrated to be gravity receptors (Cragg and Nott 1977).

2.6 PHYSIOLOGY AND EFFECTS OF ENVIRONMENTAL VARIABLES

The processes of feeding, respiration and growth in bivalve veligers have been investigated in some detail, particularly in mussels and oysters (Bayne 1983; Crisp et al. 1985; Sprung 1984a, b, c), but until recently, little was known about such processes in pectinid larvae. The studies reviewed by Bayne (1983) show that energy is acquired initially from reserves contained in the egg, then from suspension feeding; the energy obtained is partitioned for maintenance, locomotion, growth and reserves for metamorphosis.

2.6.1 Energy Reserves and Feeding

The quantity and quality of egg-derived energy reserves is important for the early stages of larval development and can be modified by alterations to adult diet (Caers et al. 1999). Larvae originating from larger-than-average eggs have a higher survival rate over the first two days of development (Kraeuter et al. 1982) and take less time to reach metamorphosis (Paulet et al. 1988). Specific fatty acids are required in the maternal diet during maturation of eggs to ensure normal embryonic development, perhaps because of the role these molecules play in cell membrane synthesis (Le Pennec et al. 1998).

The energy reserves contained in scallop eggs consist of lipids (mainly neutral lipids), proteins and carbohydrate in the form of glycogen (Whyte et al. 1992; Lu et al. 1999b). In *Argopecten purpuratus* and *A. irradians* eggs, lipids represent, respectively 34% and 27% of ash-free dry weight (AFDW), proteins 38% and 64% and carbohydrates, 1.5% and 9.5% (Farias et al. 1998; Lu et al. 1999b). Vitamins B1 and B2 are also present in the eggs and are utilised during development (Seguineau et al. 2001). Early development is fuelled by energy reserves, especially glycogen and lipid, particularly neutral lipids. Soudant et al. (1998b) found that 20-carbon polyunsaturated fatty acid levels decrease during the lecithotrophic phase of larval development. Lipid consumption provides two thirds of the energy expenditure during embryogenesis (Lu et al. 1999b). Under optimal growth conditions, the proportions of different categories of lipid remain relatively constant during the planktotrophic phase (Delaunay et al. 1992; Soudant et al. 1998b), but total lipid accumulates during planktotrophy and then acts as an energy reserve for the process of metamorphosis (Whyte et al. 1987; Delaunay et al. 1992; Farias et al. 1998; Lu et al. 1999b). Lipid content is a significant predictor of metamorphosis success (Robert et al. 1999). The use of lipid reserves bridges the period between loss of velum, and gills becoming functional (Whyte et al. 1992). During metamorphosis, all three energy reserves decline by more than 50% of their premetamorphic mass, with protein and lipid breakdown accounting for over 90% of energy consumed (Lu et al. 1999b).

Planktotrophic feeding commences shortly after the development of the shell and velum. Veligers of *Patinopecten yessoensis* are capable of ingesting cells of the alga *Isochrysis* at a rate that ranges from 50 to 700 per hour depending on larval size. These veligers can filter 3–45 μL seawater per hour (MacDonald 1988). Like mussel veligers, they filter more efficiently than oyster veligers at low food concentrations, but are less efficient at high concentrations. When they are kept under crowded conditions, ingestion

rates are reduced, perhaps due to frequent interruptions to feeding caused by collisions between larvae. Ingestion and filtration rates of *P. yessoensis* veligers are typical for bivalve veligers, as is assimilation efficiency. A food density of 6–10 cells mL⁻¹ is required to support the metabolic demands of *P. yessoensis* veligers (MacDonald 1988). However, under natural conditions, some energy demands can be satisfied by dissolved organic matter (Manahan and Crisp 1982, 1983) or perhaps from bacteria associated with organic matter in particles large enough to be captured by the feeding apparatus.

Larvae are unable to convert or biosynthesise sterols essential for development. The sterol composition of larvae is strongly influenced by that of food algae, with sterols of some algae being more readily taken up than those of others (Soudant et al. 1998a). Studies of nutrition during the planktotrophic phase (see section 2.8.2) have concentrated on experiments with defined single or multiple species algal cultures. At sea, veligers will encounter a wide variety of algal species, often at suboptimal cell concentrations. Also, blooms of less nutritious species may prejudice larval survival (Nelson and Siddall 1988). In nearshore waters dominated by ultraplankton, stomach contents of *Placopecten magellanicus* veligers were mainly composed of small autotrophic flagellates and cyanobacteria (Raby et al. 1997), the nutritional value of which has yet to be investigated.

2.6.2 Respiration

Respiration rates for pectinid veligers are markedly higher than the 1.2–10 mL O₂ g (ash free dry weight)⁻¹ h⁻¹ range for non-pectinid bivalve larvae (MacDonald 1988). Respiration rates in *Patinopecten yessoensis* veligers range from 13 to 29 mL O₂ g⁻¹ h⁻¹ and in *Argopecten irradians* veligers range from 4.6 to 15.2 mL O₂ g⁻¹ h⁻¹ (MacDonald 1988). In eyed veligers of *A. irradians* the range is 14.6–15.8 mL O₂ g⁻¹ h⁻¹ (Lu et al. 1999a). Higher respiration rates in pectinid larvae may be due to their being well fed while the other bivalves were not (Sprung, in MacDonald 1988). The high cost of respiration results in a growth efficiency, which is much lower than that of oysters or mussels (MacDonald 1988).

Respiration rates are depressed by crowding, presumably because during interruptions in swimming, the large preoral cirrus cells expend less energy. Swimming activity accounts for a considerable proportion of the energy demands of a veliger - 8–29% in the case of *Argopecten* larvae (Lu et al. 1999a). Further evidence of the energetic demands of veliger swimming is given by the much lower respiration rate of spat of *A. irradians* (1.8–5.3 mL O₂ g⁻¹ h⁻¹) (Lu et al. 1999a).

Measurement of oxygen consumption of bivalve veligers in sealed chambers by polarography yields lower estimates than by coulometric respirometry (Hoegh-Guldberg and Manahan 1995), perhaps because the latter method operates at constant dissolved oxygen levels by replacing the oxygen consumed. Measurements with polarographic electrodes or Cartesian divers in which larvae were kept in a sealed chamber should therefore, perhaps be treated as underestimates.

Respiration rate increases with body weight. This can be expressed by an equation of the form: oxygen consumption = a (body weight)^b. The value of b is close to 1 in bivalve veligers investigated to date, and is estimated at 0.92 for *Argopecten irradians* (Lu et al.

1999a) and 1.39 for *Patinopecten yessoensis* (where total rather than ash free dry weight was used: Macdonald 1988). The measured values of *b* are much higher in larvae than in adults (Lu et al. 1999a).

2.6.3 Growth

Growth of bivalve larvae can be described in terms of growth stages, cleavage rate, shell size increase or weight increase. Table 2.2 summarises the information available relating to the rate of embryological and larval development in the Pectinidae described in terms of growth stages. In most cases, this information relates to observations of larvae reared under laboratory conditions at close to optimum temperatures and feeding rates for the species in question. It is not known whether these species would develop at a similar rate in the sea, except in the case of *Patinopecten yessoensis* where development in the sea (Maru 1972) is somewhat slower than that in the laboratory (Yoo 1969). In the case of *Chlamys islandica*, the progress of a single cohort of larvae resulting from a brief spawning period in the sea near to Tromsø, northern Norway was followed (Gruffydd 1976). It was possible to estimate the length of larval life because 1) the brief spawning period was closely monitored; 2) the larvae were collected from the plankton from the earliest shelled stage until the numbers of pediveligers rapidly declined (presumably due to settlement and metamorphosis); 3) only three species of bivalve veliger were present in the plankton over the period in question and 4) the *Chlamys* larvae could be selected from these with some confidence, using features of shell morphology.

Larvae of *Patinopecten yessoensis* increase in body weight from 150 to 1,000 ng (ash free dry weight) during larval development (Whyte et al. 1987), which compares with a growth from 61 to 882 ng in *Mytilus* (Sprung 1984a). Though shell growth may not, under adverse conditions, be accompanied by growth of soft tissues (Bayne 1983), shell length measurements provide a convenient means of assessing growth. Information provided by the authors in Table 2.1 can be used to estimate shell growth rates. In general, under favourable conditions, the shells of scallop larvae grow at a rate of about 3–5 $\mu\text{m d}^{-1}$. Dissoconch growth rates are much faster (Gruffydd and Beaumont 1972; Rose et al. 1988). Larval shell growth rates give an indication of the effectiveness of feeding regimes and food species (Yoo 1969; Cary et al. 1981, 1982). The much slower rate of development of *C. islandica* larvae compared with the other species in Table 2.2 may partly be due to the lower temperatures at which these larvae were growing, but may also be due to the higher algal rations in the laboratory than in the sea where the *C. islandica* larvae were found.

Inherited factors also affect the rate of development. Different stocks of the same species may develop at different rates. In some cases, this correlates with differences in egg size (Paulet et al. 1988), but in other cases it does not (Cochard and Devauchelle 1993). The smaller larvae of a brood develop more slowly (Cabello and Camacho 1976). Experiments with reciprocal crosses between stocks with distinct larval growth rates implicate maternal effects (probably differences in quantity or quality of yolk reserves) in differences in early development rate (Cruz and Ibarra 1997). Larvae from cross-fertilised eggs develop significantly more rapidly than do those from self-fertilised eggs. This

effect of heterosis only becomes evident after about two weeks or more of development (Beaumont and Budd 1983; Ibarra et al. 1995; Cruz and Ibarra 1997).

2.6.4 Biochemical Events during Metamorphosis

In *Pecten maximus*, the levels of serotonin and dopamine, which steadily increase during larval development, drop suddenly during metamorphosis (Robert et al. 1999). Whether this is due to these molecules being concentrated in tissues lost during metamorphosis or whether they are metabolised during the process remains to be determined. Noradrenaline levels do not fluctuate in the same way. These and other molecules that affect nerve cell function have been investigated for their role in settlement and/or metamorphosis of bivalve larvae. In experiments, the molecules are generally applied to the water containing the larvae, from which they can diffuse into the larval tissues. The site of action is therefore open to debate. The fact that ions such as K^+ can trigger metamorphosis (Martinez et al. 1999) suggests a nervous signalling mechanism of the sort investigated in gastropod veligers (Hadfield et al. 2000) is implicated. The neuroactive compounds could act at the apical (sensory) membrane of chemosensory cells, at the basal (signalling) membrane of these cells, at cells deeper within the nervous system or even on the target cells for metamorphosis signals from the nervous system.

Studies with oyster larvae suggest that a dopaminergic pathway promotes settlement behaviour patterns and an adrenergic pathway controls metamorphosis (Beiras and Widdows 1995). Scallop larvae, unlike oysters, do not undergo cementation at metamorphosis and the process of metamorphosis is more protracted in pectinids than oysters (Nicolas et al. 1998). Thus, the distinction between settlement and metamorphosis is less clear. The promotion of metamorphosis by L-DOPA in *Patinopecten* (Kingzett et al. 1990) and *Pecten* (Nicolas et al. 1998) suggests a dopaminergic pathway, though *Chlamys hastata* is not affected in the same way (Hodgson and Bourne 1988). Other tyrosine derivatives, especially a quinol extracted from a rhodophyte alga, *Delesseria sanguinea* have also been shown to promote pectinid metamorphosis (Yvin et al. 1985; Chevolot et al. 1991). The increased metamorphosis rates in larvae exposed to epinephrine or norepinephrine (Kingzett et al. 1990; Nicolas et al. 1996, 1998; Martinez et al. 1999) is perhaps evidence for an adrenergic pathway.

2.7 BEHAVIOUR AND LARVAL DISTRIBUTION

2.7.1 Characteristics of Locomotion during Larval Development

Scallop larvae first become capable of movement at the gastrula stage. Initially, movement consists of undirected rolling or spinning, but by the trochophore stage, the larva swims apical cirrus first, rotating about its long axis along an upward directed path (Drew 1906; Belding 1910; Gutsell 1930; Sastry 1965; Cragg 1980). By the veliger stage, larvae swim up paths, which describe vertically orientated cylindrical helices: they rotate about their dorso-ventral axis once per complete spiral (Belding 1910; Cragg 1980). Spiralling may be in either direction (Belding 1910), but in *Pecten maximus* the direction

is clockwise in most larvae (Cragg 1980). Swimming is continuous until the veliger becomes capable of retracting the velum. Retraction may occur in response to an obnoxious stimulus (Drew 1906; Belding 1910; Comely 1972): this response (the "fright response" - La Barbera 1974) consists of an abrupt cessation of beating of the preoral cirri, followed by rapid retraction of the velum, then the closing of the shell valves (Cragg 1980). Sinking then occurs because the larval shell is much denser than water. This sequence, or the first and/or second part of it, also occurs at intervals, apparently spontaneously, so that an undisturbed larva alternates between rising and sinking. Such a pattern of swimming emerges after three days of development in *Pecten maximus*.

During the trochophore and very early veliger stages, the mean vertical velocity of *P. maximus* larvae is less than 0.5 mm s^{-1} , but later stages swim faster, with the highest mean velocity of about 1.2 mm s^{-1} recorded at the beginning of the pediveliger stage (Cragg 1980). The mean velocity of *Placopecten magellanicus* veligers ranges from 0.32 to 1.59 mm s^{-1} depending upon light, temperature and depth conditions, with the low velocities being recorded at low temperatures (Gallager et al. 1996). When the foot becomes functional, the larva sinks at increasingly frequent intervals and crawls for a while before returning to the water column (Gruffydd and Beaumont 1972; Cragg 1980; Chaitanawisuti and Menasveta 1992). The velum continues to be used for swimming during the pediveliger stage, though the foot may be extended during swimming (Hodgson and Burke 1988). Crawling is executed by a gliding motion of the foot due to its cilia, alternating with sharp jerks, which bring the shell close to the foot again (Hodgson and Burke 1988). Belding (1910) reports that after the degeneration of the velum, *Argopecten irradians* is capable of swimming by means of kicking motions assisted by the cilia of the foot. Young juveniles can enable themselves to be carried by water currents, by secreting a byssus thread that acts as a drogue (Beaumont and Barnes 1992). Swimming in the adult fashion by clapping the valves only appears some time after metamorphosis (Sastry 1965).

2.7.2 Responses to Stimuli

Locomotion alone is insufficient to keep the developing scallop in the appropriate environment. The series of types of locomotion described above are regulated by responses to environmental variables. Evidence of the sensitivity of larvae to stimuli is limited, though by the time of the pediveliger stage, the larva has a wide range of putative sense organs.

Though larval swimming is generally orientated upwards, this does not necessarily indicate the ability to detect the orientation of gravity. Several theories reviewed by Chia et al. (1984) suggest that small ciliated organisms with an anterior-posterior asymmetry and/or and asymmetrical distribution of density may move upwards, anterior end first, due to the forces generated by ciliary beating. It may be that the pectinid trochophore has an uneven distribution of lipid droplets less dense than the general cytoplasm, and the apical cirrus certainly provides a marked anterior-posterior asymmetry. When the shell is secreted, the difference in density between the shell and the velum ensures that the larva tends to swim velum uppermost (Cragg 1980). Larval shell density is between 1.20 and

1.34 depending on age (Gallager et al. 1996). The nature of the forces generated by the beating of the preoral cirri may be sufficient to account for the nature of the spiralling swimming path of the veliger without having to postulate any sensory response to environmental variables (Cragg 1989). Behavioural scientists rarely get the opportunity to vary gravity, but in an experiment in a jet travelling along a parabolic trajectory, Jackson et al. (1993) were able to do just that. They found that at the onset of microgravity conditions, the veligers of *Placopecten* change from swimming along tight spirals to swimming up steeper slopes with a wider diameter to the spiral. Given the lack of statocysts at this stage, the effect is likely to be a direct effect on the physics of the propulsion of the larva rather than a behavioural response to a detected change in the force of gravity. However, the structure of pediveliger statocysts does suggest that by this stage the larva is capable of detecting gravity, an ability which is likely to be used to orientate crawling movements, during which the shell will not impart a consistent orientation to the larva (Cragg and Nott 1977).

Sensitivity to pressure changes is widespread in marine animals without pressure-deformable structures (Knight-Jones and Morgan 1966). It has been observed in veligers and pediveligers of *Pecten maximus*, but other bivalve larvae of intertidal species appear to be more sensitive to this stimulus. The response to pressure increases was not detected in 3 day old *Pecten* larvae, but was found in larvae between 10 and 41 days old. The response consists of an increase in vertical velocity and an increased tendency to swim upwards rather than sink (Cragg 1980). Increased vertical velocity may be achieved by increasing velocity along the spiral path or by swimming up a steeper spiral (Cragg and Gruffydd 1975).

Kaartvedt et al. (1987) showed that diurnal variations in light intensity were correlated with changes in the vertical distribution of 4–20 day old *Pecten maximus* larvae in 4 m deep plastic enclosures suspended from the surface in the sea. Maru et al. (1973) examined the variation of vertical distribution of *Patinopecten yessoensis* veligers and changes in temperature, salinity and water currents throughout a 15 m water column in a shallow bay over several 24 hour cycles. They also measured light intensity at the surface. Their results indicate that veligers are distributed closer to the surface during the hours of darkness. No other correlation with environmental changes is evident in their data. They categorised larvae into size classes of less than 150 μm , 150–180 μm , 180–210 μm , and 210–240 μm (i.e., ranging from late D-veliger to umboned veliger - see Maru 1972). No difference between the light responses of the different size classes was detected. The observations of these and other (see next section) field and mesocosm studies indicate a response to light intensity changes not evident in trochophores of *Pecten maximus*, which accumulate at the surface whether they are illuminated or not (Cragg 1980). The orientation of illumination does not affect the orientation of the swimming path of veligers: the spiral path is vertically orientated whether the larva is illuminated from above, below or laterally (Cragg 1980).

Veligers swimming behaviour may be modified by changes in salinity. Gruffydd (1976) found that under laboratory conditions larvae of *Chlamys islandica* can detect salinoclines and respond by restricting their up and down movements to below the interface between a tolerated salinity and a lower salinity. In a vessel with a series of

layers of salinity with 5% reductions of salinity in succeeding layers, larvae restricted their vertical movements to those layers with a salinity of 60‰ or more of that of the seawater in which they were reared. With 20‰ salinity steps, larvae restricted themselves to water of at least 80‰ of the rearing water salinity. Culliney (1974) found that veligers of *Placopecten magellanicus* reared at 32‰ and placed in waters of 16.9‰ or 21.5‰ ceased swimming, but recovered to swim close to the bottom of their containers. Salinities of 26.2‰ and 30.0‰ produced no detectable change in their normal up and down movements. Prior exposure for 6 hours to 20‰ salinity during the trochophore stage enables veligers of *Mizuhopecten yessoensis* reared at 32‰ to maintain activity in 14‰ seawater, whereas the activity of veligers without prior exposure is markedly lower (Yaroslavl'tseva et al. 1993). It is unclear whether this is a behavioural or a physiological response.

The fright reaction can be triggered by obnoxious stimuli. These may be physical shocks such as sharp taps on the culture container (Drew 1906; Belding 1910; Comely 1972; pers. obs.) or collisions with other larvae (Drew 1906; pers. obs.). Chemical stimuli may also act as a trigger, so that in order to prevent larvae from retracting when fixatives are applied, relaxants such as $MgCl_2$ need to be gently introduced into the water in which the larvae are swimming (Cragg and Nott 1977; Hodgson and Burke 1988). It is not known whether these relaxants interfere with sensory perception or block nervous control of the musculature.

The behaviour of pediveliger larvae suggests an exploration of potential sites for settlement. Golikov and Scarlatto (1970) report that on settlement on a plant or artificial substrate, larvae of *Patinopecten yessoensis* move downwards. No studies of pediveliger responses during crawling have been carried out so the only evidence of the stimuli to which they may respond is provided by environment in which settlement occurs. In the method of rearing for *Pecten maximus*, described by Beaumont et al. (1982), no settlement substrate is provided, as this would interfere with rearing procedures, and larvae metamorphose in glass containers. Small scale experiments reported by Culliney (1974) seem to indicate that metamorphosis of *Placopecten magellanicus* is promoted by the presence of fragments of shell, glass, or sand grains, with the metamorphosed larvae showing a preference for the underside of the pieces of these materials. The observations of Culliney (1974) and Golikov and Scarlatto (1970) suggest that on settlement the juvenile scallop is positively geotropic or geotactic, or negatively phototropic. Current velocity may also affect pectinid settlement behaviour, with higher velocities near the seabed promoting settlement (Eckmann 1987).

Recently-settled pectinid spat have also been collected from many natural substrates: *Pecten maximus* and *Chlamys opercularis* have been reported from stones, empty shells, bryozoans (particularly *Cellaria*), hydroids, and the algae *Laminaria saccharina* and *Desmarestia* (Brand et al. 1980; Mason 1958); *Patinopecten yessoensis* on the algae *Sargassum pallidum* and *S. kjellmanianum*, and the seagrass *Zostera asiatica* (Golikov and Scarlatto 1970); *Argopecten irradians* on seagrasses (Thayer and Stuart 1974; Eckmann 1987); *Argopecten ventricosus* on the seagrass *Zostera marina* (Santamaria et al. 1999); *Leptopecten latiauratus* on erect bryozoans and hydroids (Allen 1979); *Chlamys islandica* on hydroid perisarc (Harvey et al. 1995b); *Adamussium colbecki* on shells of

adult conspecifics (Cerrano et al. 2001). Pectinid larvae will settle on clean silt-free surfaces of many sorts (Brand et al. 1980), including a variety of artificial substrata made from polymers (section 2.8.4). The observation that artificial spat collectors are only effective for collecting pectinid spat for about one month after immersion (Wilson 1987), suggests that the development of the primary bacterial film may modify settlement behaviour. In some cases, this may involve masking the chemical cues emanating from the surface on which the film has developed (Harvey et al. 1995b). However, promotion rather than inhibition of settlement by the primary bacterial film has been reported in several pectinid species (Hodgson and Bourne 1988; Xu et al. 1991; Parsons et al. 1993; Pearce and Bourget 1996) and older bacterial films on natural surfaces are sometimes more attractive (Harvey et al. 1995a).

In their review of settlement in pectinids, Brand et al. (1980) found no evidence for species-specific chemical settlement cues. However, Cerrano et al. (2001) found that larvae of the Antarctic scallop *Adamussium* settle on adult shells in preference to rock, though settlement density is reduced by when epizoic hydroids are present on the shell. It is not clear whether this is due to avoidance behaviour prompted by a chemical signal from the hydroids or predation by the hydroids on settling larvae. *Chlamys islandica* spat settle preferentially on the perisarc of dead rather than live hydroids or on filamentous red algae (Harvey et al. 1993). Choice experiments indicate that it is a high molecular weight protein or polysaccharide in the perisarc of hydroids that promotes settlement (Harvey et al. 1995b). Also, purified chitin from perisarc or from crustacean exoskeletons applied to artificial substrates increased the intensity of settlement on those substrates with no detectable difference between the attractiveness of different types of chitin (Harvey et al. 1997).

2.7.3 Distribution of Larvae

Laboratory experiments permit the role of individual factors in determining the distribution of larvae to be examined independently under controlled conditions, but the validity of extrapolation to field situations is constrained by the artificiality of experimental conditions (high larval densities, constraints on larval movements etc.). The use of mesocosms with much larger water volumes has improved the applicability of experimental findings, though artefacts may still complicate interpretation. For example, in mesocosms, as in smaller experimental vessels, circulation of dense aggregations of larvae may occur due to larva to larva interactions at the surface in still conditions (Gallager et al. 1996).

Field observations are constrained by the time required for counting mixed plankton samples and a reliable means of distinguishing them from larvae of other bivalves are required. The methods pioneered by Jørgensen (1946) and Rees (1950), which rely on characteristic shell outline and hinge features, have been refined by the use of SEM images (Tremblay et al. 1987). They are labour intensive to apply to large series of samples, so attempts have been made to develop alternatives. The most promising approach to date is the development of immunological probes that tag larvae of specific species or even genetically-distinct populations with fluorescent markers (Demers et al.

1993; Frischer et al. 2000; Paugam et al. 2000). Demers and colleagues used a monoclonal antibody with high specificity to the target species, but variable staining, while Paugam and colleagues used a polyclonal antibody that enabled laboratory cultures of mixed species to be separated, but did not prove effective with plankton samples. They suggest that the combination of immunological methods with minute magnetic beads may enable the sorting of plankton with a magnetic field.

Pectinid larvae have been collected in many plankton studies in neritic waters, which give information on horizontal and vertical distribution, and the temperature or season of appearance of the larvae (Table 2.4).

The timing of spawning is crucial to ensure temperatures and concentrations of phytoplankton adequate for larval development. Detailed analysis of correlations between mass spawning of *Placopecten magellanicus* and a wide range of environmental variables indicated that spawning coincided with either sharp temperature increases or with strong temperature fluctuations (Bonardelli et al. 1996). In either case, the gametes would be ejected into downwelled water masses likely to be suitable for larval development. A study of spawning of *Chlamys islandica* in the Gulf of St. Lawrence, Canada did not reveal a temperature cue, but phytoplankton blooms did appear to be associated with spawning events (Arsenault and Himmelman 1998).

Horizontal dispersal of larvae will be determined by water currents. Effects of currents on horizontal distribution have been investigated (Kulikova and Tabunkov 1974; Ito et al. 1975; Maru 1985a; Tremblay and Sinclair 1988, 1992) though conclusions are difficult to draw because of limited oceanographic information and/or because controlling factors are so complicated that there is no clear pattern. Nonetheless, there is evidence that oceanographic conditions on the continental shelf can keep different stocks of the same species of scallop separate by determining the horizontal dispersal of their larvae (Tremblay and Sinclair 1992). The extent to which larvae of shelf populations can be lost due to transport on currents from their parental area has been modelled (Tremblay et al. 1994). Tidal lagoons and estuaries offer a more constrained environment in which to investigate the effects of hydrographic conditions on dispersal. By examining the proportions and numbers of different larval stages, Maru (1985a) produced a budget for larval development within a lagoon, calculating egg production, death, loss due to outflow and settlement. Larvae of *Argopecten irradians* were found in greater numbers in the upstream part of an estuarine system, a distribution attributed by Moore and Marshall (1969) to asymmetry in the tidal circulation pattern, but also explicable in terms of vertical migration in response to salinity as inferred in the study of *Crassostrea* larvae by Wood and Hargis (1971).

Larvae may have some control over their vertical distribution. In the laboratory in the dark, trochophores of *Pecten maximus* accumulate in the upper few centimetres of a shallow vessel (as do trochophores of *Chlamys hastata* - Hodgson and Burke 1988), but once larvae develop a closable shell, they become distributed more evenly through the water column. By the late veliger stage, there is no concentration of larvae near the surface and, on reaching the pediveliger stage, most larvae accumulate just above the bottom (Cragg 1980). Early veligers of *Argopecten irradians* and *Placopecten*

magellanicus also tend to be found near the surface while later stages occur near the bottom of their containers (Belding 1910; Sastry 1965; Culliney 1974).

In 9 m deep laboratory mesocosms with only limited water movement, *Placopecten* veligers from 6 to 49 days old tend to concentrate in the top 10 cm, especially at night, irrespective of the distribution of their food microalgae, except in the case of larvae larger than about 240 µm, which become evenly distributed through the water column (Gallager et al. 1996). A thermocline in the mesocosm of greater than 1 degree C may constrain the extent of vertical movement of larvae, leading to a concentration of larvae above the thermocline (Manuel et al. 2000).

Vertical distribution of larvae in the sea is more variable, partly because of the much greater water depths involved, but perhaps also because of vertical water movements (Maru 1985a). Developmental stages of *Chlamys islandica* from D-veligers to

pediveligers were found in a fjord at the surface and at 40 m depth, but there were few larvae at 100 m (Gruffydd 1976). Veligers of *Pecten maximus* showed no clear vertical distribution in depths of up to 25 m (Sasaki 1979). However, most larvae of *Patinopecten yessoensis* were found within 8 m of the bottom in depths of 16–24 m in Yeong-il Bay, Korea (Yoo and Park 1979), while larvae of the same species from 170 to 275 μm in length were distributed from the surface to near the bottom at 14 m (Grigor'eva and Regulev 1992). Larvae of the same species in 15 m depth in a tidal lagoon in northern Japan with no marked temperature or salinity gradients, showed no clear difference between the distribution of different size classes from D-veliger to late veliger (Maru et al. 1973; Maru 1985a). No consistent pattern of *Placopecten magellanicus* veliger size distribution over the top 40 m in the Bay of Fundy was detected, but the mean size of veligers just above the seabed was slightly greater than that of larvae taken in vertical tows from 5 m above the seabed (Tremblay and Sinclair 1988). When the water column was well mixed, veligers were distributed almost evenly over the top 40 m, but when a thermocline was present, veligers were sometimes unevenly distributed with a peak associated with the thermocline (Tremblay and Sinclair 1990a). The vertical distribution of food organisms, whether at sea or in a mesocosm, rarely shows any evidence of affecting the distribution of veligers (Raby et al. 1994; Manuel et al. 1996 a, b).

Diurnal vertical migration by scallop veligers has been detected in mesocosms with artificial lighting providing a day-night cycle of illumination (Manuel et al. 1996 a, b), in mesocosms suspended in the sea under ambient lighting (Kaartvedt et al. 1987) and in the sea (Maru 1985a; Tremblay and Sinclair 1990b; Raby et al. 1994). Larvae from different parental stocks may show different intensities of vertical migration, even when kept in the same container (Manuel et al. 1996 a and b). Data from mesocosm and field studies of *Placopecten* veligers can be fitted to a tidal diel model, with tidal response varying from stock to stock in a way that ensures that pediveligers are adapted to the current regime of the larval and parental environment. There strong selection pressure imposed by the advective loss of larvae, which would favour the development of behavioural responses to diel and tidal cues appropriate to the particular environment (Manuel et al. 1997).

The vertical distribution of settlement of pectinids has also been examined. Spat may occur in surface plankton tows (Gruffydd 1976). The natural settlement of *Patinopecten yessoensis* on the western shores of the Sea of Japan occurs at depths of 1–3 m (Golikov and Scarlatto 1970), perhaps determined by the distribution of the settlement substrates - seagrass and algae. Patterns of vertical settlement distribution on artificial settlement substrates include: increasing with depth (*Chlamys islandica* - Wallace 1982; *Pecten maximus* - Sasaki 1979; *Patinopecten yessoensis* - Maru 1985a); increasing with depth but decreasing just above the bottom (Naidu and Scaplen 1976); fairly even, but less intense near the surface and bottom (*Pecten maximus* Brand et al. 1980; *Pecten fumatus* - Hortle and Cropp 1987); reducing with depth (*P. yessoensis* - Evans et al. in Brand et al. 1980). Different species of scallop at the same site have been shown to have different depth preferences at sampling depths of 20, 50 and 70 m (Peña et al. 1998). Factors controlling vertical distribution of settlement have been examined in experiments in 9.5 m deep mesocosms. In turbulent conditions, there was no effect of depth on settlement, while in low turbulence conditions settlement rate increased with depth and weak temperature

stratification (approximately 1.5 degrees C) did not affect settlement distribution (Pearce et al. 1998). Strong stratification (approximately 4 degrees C) did limit settlement to above the thermocline and vertically stratified food distribution had an adverse effect on settlement (Pearce et al. 1996).

2.7.4 Development and the Larval Environment

Direct observation of scallop larvae in their natural environment presents considerable practical difficulties and plankton sampling provides only isolated snapshots of larval distribution. Nonetheless, the information reviewed above does permit predictions about the nature of larval life of pectinids in the sea to be made. The larval period can be considered to consist of three phases characterised by the nature of the energy source used and the nature of locomotion. The first phase is lecithotrophic, the second and third are planktotrophic with swimming the only type of locomotion in the second and crawling alternating with swimming in the third.

The embryonic phase is the most vulnerable to environmental conditions. The survival of larvae during this phase is dependent on spawning taking place when conditions are suitable for embryological development (see for example Broom and Mason 1978; Bonardelli et al. 1996). Passive orientation of swimming (see above) is probably sufficient to ensure that the early larvae move up into the water column from the adult environment to the larval environment. The apical flagellum may warn of the forces of surface tension that could rip the naked larva apart.

On becoming able to feed, the larva enters the dispersal phase. It moves up and down due to its own efforts, but lateral (dispersal) movements are due to water currents. The trigger that prevents the larva from sinking out of the water column is likely to be the resulting increase in pressure. The diurnal migrations observed by Maru et al. (1973), Kaartvedt et al. (1987) and Manuel et al. (1996a, b) may reduce the risk of predation by moving the larvae in response to rising light intensity into less well illuminated, deeper waters during the day. The fright reaction may also serve to protect larvae from predation and from surface tension effects in bursting bubbles. The response to lower salinity observed by Gruffydd (1976) would tend to prevent a larva passing up through a salinocline such as may occur in the enclosed waters in which the larvae of many pectinids are found (see for example, Moore and Marshall 1969). Temporary reductions in temperature may not be fatal at this stage as larvae can survive a temperature-induced arrest and continue development when the temperature rises again (Beaumont and Budd 1982). During this phase, larvae may be carried far from their parental stock (Tremblay and Sinclair 1988).

The third phase of larval life may be considered to serve to enable the larva to find a suitable settlement substrate. The fact that the larva does not abandon swimming altogether increases the area the larva can explore, because lateral dispersal may occur during each period of renewed swimming effort. Furthermore, the larva is able to feed during swimming so that energy reserves are maintained. During crawling movements, the sense organs developed in the late veliger larva may come into play: the statocysts to

orientate crawling and perhaps some of the ciliated cells of the mantle to test the nature of the substrate.

During the embryonic phase, the chances of survival are affected by the prior spawning response of adults to environmental cues. During the dispersal phase, swimming behaviour has survival value; settlement behaviour permits the larva to be selective about the site for metamorphosis and juvenile life. Thus, the larva is not a passively dispersed "seed": the high risks of larval life are reduced by adult behaviour and the larva has some control over its own destiny.

Dispersal in species with small adult size and a patchy adult environment such as hydrothermal vents or submarine caves must require different mechanisms, particularly in brooding species. Hayami and Kase (1993) hypothesise that the colonisation of cave environments by non-planktotrophic species may occur as a result of pseudoplanktonic dispersal of juvenile attached to current-carried debris, though dispersal independent of attachment, by byssus drifting (Beaumont and Barnes 1992; Wang and Xu 1997) might also provide the necessary dispersal mechanism.

2.7.5 Tolerance of Environmental Variables

Light intensity is not normally considered as a factor limiting larval development or survival and light conditions are frequently not mentioned in experimental descriptions, but Krasso et al. (1997) showed that high light intensities correlate with high levels of abnormal development in *Chlamys asperrima*.

Temperature is a key variable for larval development. Too low a temperature reduces or arrests growth (Beaumont and Budd 1982) while too high temperatures may permit rapid growth of harmful bacteria and ciliates in the culture, cause high mortality rates (Gruffydd and Beaumont 1972) or increased levels of abnormal embryos (Krasso et al. 1997). Temperature optima may vary during embryonic and larval development (Heasman et al. 1996): this may represent adaptation to the differences in temperature between the embryonic, benthic environment and the larval environment – the euphotic zone. Optimum development of *Patinopecten yessoensis* embryos occurs at 20°C: development rate decreases with decreasing temperature, but still occurs even at 4°C; a decrease is also evident at 23°C and at 28°C no development takes place (Maru 1985b; Park et al. 2001). Temperature changes increase mortality of early cleavage stages, trochophores and D-veligers of *Argopecten irradians*, with mortality increasing with longer periods of exposure to suboptimal temperatures. Cleavage stages are most sensitive to thermal shock and veligers least (Wright et al. 1984). This species is more sensitive than non-pectinid bivalves (Wright et al. 1983). Temperature tolerance limits during the larval phase may determine adult distribution (Beu 1999).

Most rearing of pectinid larvae has been carried out using the seawater supply also used for the maintenance of the adults, with salinities within the range 30–35‰. Reduced salinities severely affect embryonic development and adversely affect growth of veligers (Gruffydd and Beaumont 1972; O'Connor and Heasman 1998). Embryonic development of *Patinopecten yessoensis* can take place over the range of about 14 to 21.5‰ salinity with a marked reduction in the rate of development at either end of this range (Maru

1985b). In *Chlamys asperrima*, percentage normal development declines sharply above and below the optimum salinity range of 31–33‰ (Krasso et al. 1997). Gruffydd (1976) found that the survival of *Chlamys islandica* veligers over a 24-h exposure period was little affected by salinities as low as about 21‰, but markedly reduced at 14‰, with 100% mortalities at 7‰. Culliney (1974) noted that veligers of *Placopecten magellanicus* could survive for 48-h at salinities as low as 10‰, though there was evidence of tissue swelling and the larvae were incapable of normal swimming. The tolerance of reduced salinity varies according to whether larvae experience an abrupt reduction or a gradual transition (Davenport et al. 1975). If salinity fluctuates with a diurnal sinusoidal regime (as it might under an estuarine tidal regime) from a maximum of about 33.5 ‰, the salinity LC50 for *Pecten maximus* larvae is about 8‰, but abrupt changes give a LC50 of 16.6‰ and for constant low salinities the LC50 is 12‰ (Davenport et al. 1975). Also, the salinity tolerance range may be increased by prior exposure to suboptimal salinity (Yaroslavtseva et al. 1991).

The possibility of synergistic effects between sublethal salinities and temperatures has been investigated by mapping the tolerance of embryos and/or larvae of *Pecten maximus*, *Argopecten irradians* and *Mimachlamys asperrima* to a range of temperature/salinity combinations (Davenport et al. 1975; Tettelbach and Rhodes 1981; O'Connor and Heasman 1998). *P. maximus* veligers were exposed to the test temperature/salinity combination for a period of 24-h, returned to normal culturing conditions and after a recovery period were examined for activity of preoral cirri which was used as an index of survival. Their temperature tolerance was greatest at salinities close to 34‰. Prior to experimentation, *Argopecten irradians* embryos and larvae were kept at a salinity of 25‰ – close to that of the environment from which brood stock were obtained. Measurements were made of embryonic development, growth and survival of veligers at combinations of temperatures from 10 to 35°C and salinities ranging from 10 to 35‰. Normal embryonic development only occurred over a narrow range of salinities, while survival of veligers was markedly reduced at salinities of 15‰ or less, particularly at 10 and 20°C. Growth rates were greatest between 20 and 30‰ at 25–30°C, but were markedly reduced when both temperature and salinity fell outside these ranges. The tolerance of *Mimachlamys asperrima* to suboptimal temperatures and salinities varied over the period of development.

Pollutants affect the viability of scallop larvae in a number of ways. Parental exposure to heavy metals may result in gametes with elevated levels of phosphatases that give rise to embryos and early veliger larvae which also have elevated levels of these enzymes and which fail to develop normally (Karaseva and Medvedeva 1993). Larval exposure to organic pollutants and heavy metals also disrupts development (Liao and Li 1980; Beaumont et al. 1987; Krasso et al. 1997). Settlement behaviour appears to be affected by organotin antifoulants (Minchin et al. 1987). Embryonic stages of bivalves are particularly sensitive to pollutants. This sensitivity has been exploited in the development of the D-larva bioassay in which the appearance of the characteristic D-shaped early veliger shell is used as a marker for normal development (Anonymous 1994; His et al. 1999). This ecotoxicological test is usually performed with oyster or mussel embryos, but *Chlamys asperrima* embryos show comparably high sensitivities to a range

of pollutants (Krasso et al. 1997; Pablo et al. 1997). Other bioassay tests have been developed with bivalve larvae. Changes in the parameters of larval swimming trajectories have been used to bioassay sublethal effects of pollutants (Praël et al. 2000) and of toxic algae (Yan et al. 2001, 2002). Improvements with cryopreservation techniques to permit storage of viable larvae or gametes would improve comparability of tests and would facilitate the use of pectinid larvae, which are more demanding of rearing conditions.

2.8 REARING METHODS

2.8.1 Spawning and Manipulation of Zygotes

Descriptions of larval rearing methods are available for most of the pectinid species listed in Table 2.1. Rearing of *Hinnites multirugosus* is described by Cary et al. (1981, 1982). Additional information on the rearing of *Patinopecten yessoensis* is provided by Yoo and Imai (1968) and on *Pecten maximus*, by Comely (1972) and Beaumont et al. (1982). The methods used are similar to those described by Loosanoff and Davis (1963), but pectinid larvae seem to be particularly sensitive to rearing conditions (Tettelbach and Rhodes 1981; Beaumont et al. 1987).

Some species are amenable to being brought into spawning condition in the laboratory so that larvae can be produced at most times of the year, while others seem restricted to the spawning period of the wild stocks (Beaumont et al. 1982; Gruffydd 1976). Subjecting ripe adults to a rise in temperature of about 5 degrees C is the spawning stimulus used for most pectinids, but Le Pennec (1982) found *Chlamys opercularis* to require more carefully regulated stimulation: he evaluated the efficacy of a variety of sequences of temperature change or UV stimulus, but concluded that the most important factor was the sexual cycle of this species. Induction of spawning in *Mimachlamys asperima* by intragonadal injection of serotonin gives similar yields of larvae to spawnings induced by thermal shock (O'Connor and Heasman 1995). Stripped spermatozoa achieve lower fertilisation rates and produce more abnormalities than those obtained from induced spawning (Beaumont and Budd 1983). Most authors endeavoured to minimise self-fertilisation as larvae thus obtained grow more slowly and fewer survive to metamorphosis (Beaumont and Budd 1983; Ibarra et al. 1995). The proportion of sperm to eggs needs to be controlled so that the incidence of polyspermy is minimised (Gruffydd and Beaumont 1970; O'Connor and Heasman 1995; Desrosiers et al. 1996).

Treatment at meiosis I or II with heat or cold shock, pressure or cytochalasin B induces triploidy: higher heterozygosity is retained if meiosis I is targeted (Beaumont and Zouros 1991). Heat shock treatment does not affect larval growth rate (Toro et al. 1995). A brief treatment with the puromycin analogue 6-DMP inhibits polar body extrusion and chromosome movement, but as it is water-soluble it can be washed out from cultures once triploidy has been induced, to avoid compromising embryo viability (Desrosier et al. 1993). This offers the possibility of rearing scallops in which growth is focused on somatic tissues.

Conditioning of adults for spawning is a protracted and not always reliable procedure. It should not only be designed to bring the adults into spawning condition, but also to

ensure egg quality, which is a major determinant of larval survival and growth (Caers et al. 1999). When spawning is successful, it generally produces far more larvae than are required. Cryopreservation offers the possibility of storing excess larvae. Odintsova and Tsal (1995) investigated the efficacy of dimethyl sulphoxide (DMSO), glycerol, taurine and bovine serum albumin as cryoprotectants for cultures of bivalve cells. They found that the viability of cells from early veligers could be maintained if protected by 10% DMSO or 10% glycerol. Trochophore cells lost viability under the same conditions. Perhaps this approach could be tailored to protect whole larvae.

2.8.2 Feeding

Larvae have been cultured generally at densities of 10 per mL or lower, though Ibarra et al. (1997) found that densities up to 20 per mL gave satisfactory growth rates. Higher densities depress growth rates of *Pecten maximus* (Gruffydd and Beaumont 1972) and densities above two per mL are sufficient to markedly reduce long-term larval survival in *Patinopecten yessoensis* (MacDonald 1988).

Cultures are supplied with food in the form of single celled algae, which vary in their nutritional value. For example, *Isochrysis galbana*, particularly in the stationary phase of culture when the cells have a high lipid content, proved a superior food for *Hinnites balloti* larvae than *Pavlova lutheri*, *Rhodomonas* sp. and the chlorophyte, *Carteria pallida* (Cary et al. 1981). Though *Chaetoceros calcitrans* gives good growth rates, it does not support metamorphosis (Soudant et al. 1998a). Mixtures of two or three algal species may give higher growth rates (Gruffydd and Beaumont 1972; Narvarte and Pascual 2001). Mixed diets also ensure the uptake of a broader range of sterols (Soudant et al. 1998a). The algae used come from a range of taxa: diatoms (*Chaetoceros*, *Phaeodactylum*, *Thalassiosira*); chlorophytes *Dunaliella*, *Nannochloris*, *Tetraselmis*; chrysophytes (*Isochrysis*, *Pavlova*); cryptophytes (*Rhodomonas*) (see references in Table 2.1). Epifluorescence studies revealed that veligers of *Pecten maximus* and *Argopecten ventricosus* readily ingest and digest *Pavlova lutheri* and *Isochrysis galbana*, but that *Dunaliella promolecta* is less readily ingested and is poorly digested, and *Tetraselmis suecica* is poorly ingested if at all and is not digested (Le Pennec and Rangel Davalos 1985; Lora-Vilchis and Maeda-Martinez 1997). *A. ventricosus* ingests but does not digest *Nannochloris oculata* or *Phaeodactylum tricornutum*. The concentration of food organisms supplied is important: depending on size, *Patinopecten yessoensis* larvae require from 7 to 15 cells per μL to obtain sufficient energy to permit growth (MacDonald 1988). Growth rate of *Argopecten irradians* veligers increased with increasing concentration from one cell per μL up to an optimum of 20 cells μL^{-1} (Lu and Blake 1996a, b).

The culture water is changed every two or three days. Algal feed is added after the change, having been centrifuged (Gruffydd and Beaumont 1972) to prevent too much of the algal growth medium entering the culture.

Larvae are capable of ingesting and digesting bacteria. It is likely that though the estimated uptake of bacterial cells can be high ($>10,000$ cells larva $^{-1}$ d $^{-1}$), the contribution

to nutrition is qualitative rather than quantitative (Moal et al. 1996), with bacteria supplying vitamins absent in the food algae (Seguineau et al. 1993).

2.8.3 Control of Disease in Cultures

High mortalities in scallop cultures can be caused by viruses: a herpesvirus has been detected in cellular lesions in scallop and oyster larvae (Arzul et al. 2001). The causative agent of paralytic shellfish poisoning, the dinoflagellate *Alexandrium tamarense* depresses embryonic development and survival of *Chlamys farreri* larvae (Yan et al. 2001). However, bacteria are the main cause of mass mortalities in laboratory and hatchery culture (Nicolas et al. 1996; Robert et al. 1996). They may be brought into larval cultures via seawater, air, brood stock or algal cultures (in which they flourish due to the elevated nutrient levels) (Sainz et al. 1998). *Aeromonas hydrophila* and *Vibrio alginolyticus* have been associated with mass mortalities of *Argopecten purpuratus* larvae (Riquelme et al. 1996a). A *Pseudomonas* has been implicated in necrosis in *Euvola* larvae (Lodeiros et al. 1992). Velar necrosis has been regularly detected in cultures of *Pecten maximus* in which antibiotics were not used (Nicolas et al. 1996). The mechanism of infection in this case may be a combination of invasion of larval tissues and build up of toxins. Isolates from moribund larvae in these cultures include a vibrio that is specific to scallop larvae, *Vibrio pectinica* (Lambert et al. 1998). A small, heat-stable and protease-resistant molecule that is toxic to *P. maximus* haematocytes has been extracted from the cytoplasm of *V. pectinica* (Lambert et al. 2001). *Vibrio alginolyticus* has been found to infect *Argopecten purpuratus* larvae (Jorquera et al. 1999), causing diminished swimming, empty stomachs, formation of lipid granules in the gut, and velar necrosis or even detachment. These effects are due to an exotoxin protease that affects cilia and collagen (Sainz et al. 1998).

At each water change, culture containers can be sterilised with bleach, as can the larvae, provided care is taken to expose them briefly and only to low concentrations. The water used is filtered to 0.2 µm and UV sterilised (Gruffydd and Beaumont 1972). Antibiotics such as chloramphenicol, penicillin, sulphamethazine and streptomycin have been added to larval cultures to minimise bacterial build-up between water changes. In a closed system, the use of chloramphenicol has been demonstrated to improve growth and survival rates of veligers of *Argopecten purpuratus* (Uriarte et al. 2001). Torkildsen et al. (2000) established minimum inhibitory concentrations against bacteria isolated from scallop cultures for a range of antibiotics, with a view to providing alternatives to chloramphenicol, which is banned for use with animals intended for human consumption in many European countries.

The rearing method described by Beaumont et al. (1982) does not require antibiotics. Effective upwelling and downwelling flow-through systems have been developed which reduce the numbers of bacteria without compromising growth rate (Andersen et al. 2000), while enhancing metamorphosis rates (Robert and Nicolas 2000).

Some bacteria isolated from larval cultures produce substances that inhibit pathogenic bacteria (Riquelme et al. 1996b). These include members of the genera *Vibrio*, *Pseudomonas* and *Bacillus* (Riquelme et al. 2001). *Roseobacter* sp. produces a substance

when in the presence of *Vibrio anguillarum* that enhances survival of scallop larvae: the substance is trypsin susceptible and stable at 100°C (Ruiz-Ponte et al. 1999). A substance produced by *Vibrio anguillarum* that has an inhibitory effect on the pathogen of *Argopecten purpuratus* has been characterised as an aliphatic hydroxyl ether (Jorquera et al. 1999). The potential of co-culturing such bacteria with food algae is under investigation (Riquelme et al. 1997; Avendaño and Riquelme 1999) and their addition to cultures has been shown to permit larvae to complete the planktotrophic phase without the need for antibiotics (Riquelme et al. 2001). Indeed, antibiotics might adversely affect the balance between probiotic and pathogenic bacteria. Veliger larvae have been shown to be capable of ingesting probiotic bacteria (Riquelme et al. 2000), which thus may provide a nutritional as well as bacteriostatic benefit.

2.8.4 Collection of Spat from Wild Stocks

The process of preparing brood stock, controlling spawning and rearing larvae through to metamorphosis requires considerable investment in equipment and skilled personnel. An alternative, in areas where sufficient numbers of larvae occur in the plankton, is to place collectors with a suitable substrate for larval settlement into the larval environment and to transplant the metamorphosed juveniles to aquaculture facilities. This approach has been used with considerable success in relatively enclosed waters in Japan (Ventilla 1977).

A variety of artificial settlement substrates have been successfully used: cotton nets, unravelled sisal ropes, birch brooms (Golikov and Scarlatto 1970), rice straw ropes, cedar twigs, scallop shells, monofilament net, Netlon (Ventilla 1977) or polyethylene film (Naidu and Scaplen 1976). *Aequipecten tehuelchus* settles more readily on monofilament Netlon inside a bag of 2 mm mesh than on monofilament onion bags or thin branches (Narvarte 2001). *Chlamys islandica* settles on nylon filaments of 0.15 mm diameter in preference to those of 0.8 mm or thicker (Wallace 1982). The rock scallop, *Hinnites multirugosus* settles in much greater numbers on gill net collectors than on stick collectors, but *Leptopecten latiauratus* settles readily on both types (Phleger and Cary 1983) and on virtually any artificial surface, and on live kelps (Morton 1994). Pearce and Bourget (1996) found that *Placopecten* settled in much greater numbers on polyester filter wool than on various diameters of monofilament nylon, onion bag material, polyethylene turf, acrylic sheets, or adult shells. Shape and dimensions rather than the chemical nature of the material appear to influence settlement, perhaps by modifying small-scale water flow patterns. Except under static hatchery conditions, larvae encountering a spat collector may be subject to turbulent flow in the immediate vicinity of the collector surfaces, which will affect the chances of the larva attaching. Miron et al. (1995, 1996) investigated the likely effect of collector design on larval velocity, trajectory within a collector by using an artificial flow regime in a flume and video endoscopy to follow passive movement of larva-sized particles.

Timing of the deployment of spat collectors to coincide with the availability of metamorphically competent larvae requires detailed information. Ito et al. (1975) give an example of the sort of information needed. They studied the relationship between

appearance of *Patinopecten* larvae, settlement, and daily temperatures in the months proceeding spawning. Factors such as the time required for primary film formation on collector surfaces also have to be taken into account (see section 2.7.2 above).

Chapter 3

Structure and Function in Scallops

Peter G. Beninger and Marcel Le Pennec

3.1 INTRODUCTION

At the beginning of the 1990's, the field of bivalve anatomy and function was characterised by hundreds of disparate papers, often based on extremely rudimentary techniques, in journals that often no longer exist. Since the publication of the first edition of this volume (Shumway 1991), two other works presenting modern compilations of bivalve anatomical and functional data have appeared, each focussing on a particular species: The Eastern Oyster *Crassostrea virginica* (Kennedy et al. 1996), and Biology of the Hard Clam (Kraeuter and Castagna 2001). A general presentation of bivalve micro-anatomy has appeared in the Microscopic Anatomy of Invertebrates series (Morse and Zardus 1997). In addition to the constitution of very important information resources, each of these works has considerably raised the profile of bivalve anatomy and function, while at the same time rendering the field accessible and comprehensible to non-specialists.

The common term 'scallop' may be used to designate members of the superfamily Pectinoidea, which includes the extant families Pectinidae, Entoliidae, Spondylidae, and Propeamussiidae (Waller 1991). Since the other families of this group either have alternate common names (the Spondylidae are also called 'thorny oysters') or are poorly known to non-specialists (the Propeamussiidae are small, very poorly-known deep-water species, while the Entoliidae are represented today by only one known species, described as 'very rare, cryptic, and surviving only in disjunct populations in the Caribbean and central and Western Pacific ocean' (Waller 1991)), we will herein restrict the term 'scallop' to members of the family Pectinidae, which are the subject of this chapter. The deep-sea *Bathypecten* genus will be excluded, because *Bathypecten vulcani* is, in fact, a propeamussiid (Dufour et al. in press).

3.1.1 An Overview of the Scallop Body

The family Pectinidae displays one of the greatest degrees of anatomical differentiation within the Bivalvia. Organs are quite distinct and easily located; although this facilitates the anatomical study of scallops, one is quickly impressed with the complexity of the body systems themselves.

Until the 1980's, much of the state of our knowledge concerning scallop anatomy had been derived from meticulous studies performed in the late nineteenth and early twentieth

centuries, when observational techniques were still quite limited. Although a prodigious body of knowledge was built up by the work of Kellogg (1892, 1915), Drew (1906), and Dakin (1909, 1910a, b), it is appropriate to integrate more recent observations of scallop anatomy and function using the techniques now available. Accordingly, much of the emphasis in this chapter will be placed upon the results of more recent studies of scallop structure and function.

One of the earliest detailed descriptions of scallop general anatomy was that of Drew (1906). Other general descriptions of overall anatomy in various scallop species may be found in Kellogg (1892), Gutsell (1931), Pierce (1950), Yonge (1951), Bourne (1964), and Mottet (1979). As the structure of the shell, the adductor muscle and the larva have been treated elsewhere (Waller 1991; Chapters 2 and 4 in this work), only the postlarval soft body parts with the exception of the adductor muscle will be presented here (Fig. 3.1). Despite some inter-taxon anatomical variation, the following general overview of the scallop body may be considered representative.

The Pectinidae and other monomyarians are characterised by several important modifications of the more primitive isomyarian body form. The region corresponding to the isomyarian “anterior” is greatly reduced, such that the anterior adductor muscle is completely absent. Similarly, the isomyarian “ventral” region is shifted anteriorly, the foot being quite close to the mouth. The inadequacy of such conventional terms as anterior and ventral when describing scallop anatomy has been pointed out by Yonge (1951); Stasek (1963) has recommended that such terms not be used to refer to orientation, but rather to the relation of body parts with one another. While such an approach is technically justified, it would render the present text confusing to those less familiar with bivalve anatomy. For the sake of simplicity, the term “dorsal” will be considered to indicate those structures closest to the hinge line, while the term “anterior” will be used to designate those structures closest to the extreme point of the shell margin on the side where the mouth is located. The terms “ventral” and “posterior” will of course refer to the opposite directions, respectively, of the proceeding. The large posterior adductor muscle, situated near the centre of the shell, serves as a convenient reference point for the other body parts.

The internal shell faces are covered by a very thin, transparent mantle, which thickens and divides into distinct folds at the shell margin. The most evident of these folds is the mantle curtain, or velum, which modulates the exit of water from between the valves during valve adductions, such as the rejection of pseudofeces and the swimming response. The margin of the mantle carries a large and variable number of sensory tentacles and eyes.

The heart is contained within a thin, transparent pericardium immediately dorsal and slightly posterior to the adductor muscle. It is composed of two auricles and a single, large ventricle from which an anterior aorta extends antero-dorsally, while a posterior aorta arises from the ventricle and curves around the ventral margin of the adductor muscle. These two vessels then ramify to form the peripheral arterial system. The venous system is chiefly composed of a number of sinuses from which the blood flows through the kidneys to the gills. Blood from the gills enters the corresponding right or left auricle via an efferent branchial vessel.

Figure 3.1. General anatomy of a large pectinid, *Placopecten magellanicus*. Figure 3.1.1. Left shell and mantle removed. Figure 3.1.2. Left shell, mantle and gill removed. Abbreviations: ABV, afferent branchial vessel; AU, auricle; C, chondrophore; DB, dorsal bend of gill filaments; EBV, efferent branchial vessel; F, foot; G, gill; GO, gonad; I, intestine; K, kidney; L, lips; LP, labial palp; M, mantle; O, oesophagus; PC, pericardium; PV, pallial vessels; R, rectum; S, stomach; ST, sensory tentacle; SMAM, smooth adductor muscle; STAM, striated adductor muscle; V, velum. After Drew (1906).

The paired kidneys are attached directly to the anterior margin of the adductor muscle. The kidneys open internally into the anterior region of the pericardial cavity, and externally into the common uro-genital pore at their ventral extremity.

The gonad of sexually mature scallops is also directly attached to the anterior margin of the adductor muscle, covering the kidneys. It curves around the ventral margin of the adductor muscle, where it is unattached. In some species, such as *Hinnites multirugosus* and *Placopecten magellanicus*, gonadal tissue may extend dorsally into the labial palps, digestive gland, or mantle from its anterior end (Yonge 1951; P.G. Beninger, unpublished personal observations). The foot and its associated byssal complex arise from the antero-dorsal extremity of the gonad, being attached to the left valve by a single pedal retractor muscle, which is variably developed in different species.

Ventral to the gonad are the two large gills, which are attached to the adductor muscle via suspensory membranes on the right and left insertions of the muscle to the shell. The relaxed gill follows the curvature of the shell margin, from the postero-dorsal level of the adductor muscle to a point just ventral to the anterior hinge margin. Each anterior gill extremity is enveloped on the right and left sides by the paired labial palps, which themselves become greatly folded to form the dorsal and ventral lip-apparatus, covering the mouth.

The oesophagus leads directly to the stomach, which is situated within the digestive gland, just ventral to the chondrophore. The intestine describes several loops in the digestive gland, which it exits posteriorly, descends ventrally and enters the gonad at its most antero-dorsal extremity. After a single elongated loop in the gonad, the intestine curves around the dorsal portion of the adductor muscle and up toward the hinge line, descends ventrally and traverses the pericardium and ventricle. The distal portion of the intestine is attached to the posterior side of the adductor muscle, becoming free in the region of the rectum and anus.

Although transparent and therefore somewhat difficult to see, the most conspicuous parts of the scallop nervous system are the two ganglionic concentrations. The parietovisceral ganglion is located on the antero-ventral surface of the adductor muscle. It innervates the adductor muscle, ventral mantle region, gills and some viscera. The fused pedal and cerebral ganglia are slightly ventral to the mouth, and are linked to the parietovisceral ganglion by a pair of cerebro-visceral connectives. These ganglia and connectives innervate the rest of the scallop body.

3.2 THE MANTLE AND ITS DERIVATIVES

The scallop mantle is a two-faced epithelial membrane, which intervenes in several key functions, such as secretion of the shell and ligament, sensory perception, and swimming response via the velum. Its role in pallial water circulation is probably minor, given its patchy cilia distribution (see below).

3.2.1 Gross Functional Anatomy

The mantle is composed of a sparsely-ciliated (Fig. 3.2) right and left lobe, which are fused dorsally along the cardinal plate and closely connected to the adductor muscle, digestive gland and pericardium. The two thin lobes separate from the visceral mass at the base of the gills, enclosing the large ventral pallial cavity. They are connected to the right and left shell valves by strands of connective tissue terminating in specialised tendon cells (Bubel 1984). At the mantle margin are found the various folds and grooves, including the numerous eyes and tentacles.

Although in the Pectinidae there are no specialised fused mantle regions to form siphons, the inhalant and exhalant currents follow definite trajectories due to the directed beating of the gill cilia. Thus, in *Pecten maximus* and *Chlamys opercularis* inhalant currents are created around the entire mantle, with the exception of a narrow postero-dorsal region where an exhalant current is evident (Dakin 1909; Ghiretti 1966). Similar observations have been made by Kellogg (1915) on *Placopecten magellanicus* and *Argopecten irradians*.

The free edges of the mantle lobes are well-developed and divided into three folds and two grooves. The terminology for these structures in the Pectinidae is derived from the studies of Drew (1906), Dakin (1909), Gutsell (1931) and summarised for bivalves in general by Petit (1978). The recent interest in bivalve functional anatomy has resulted in excellent presentations of the mantle lobes and periostracal formation in non-pectinid species (Morse and Zardus 1997; Eble 2001). Beginning with the most external formation, it is possible to identify the following (Fig. 3.3):

- an external or shell fold, subdivided into a primary shell fold, a periostracal groove, and a secondary shell fold;
- an external groove;
- a middle or sensory fold;
- an internal groove;
- an internal or velar fold;

The small shell fold contains the periostracal groove, which constitutes the glandular system responsible for secretion of the periostracum. Although Dakin (1909) states that this fold bears long, extensible tentacles in both *Pecten maximus* and *Chlamys opercularis*, none are reported for either *Argopecten irradians* (Gutsell 1931) or *Placopecten magellanicus* (Drew 1906; P.G. Beninger, personal observations). The shell fold of *P. magellanicus* does, however, bear numerous short tentacles (Moir 1977a) which respond to tactile stimulation (P.G. Beninger, unpublished observations), while long, extensible sensory tentacles are situated slightly medially to the eyes at the lateral margin of the more well-developed middle mantle fold (also called the ophthalmic or sensory fold). The eyes are considered in detail in Chapter 5 and the sensory tentacles in section 3.8.2.2 of the present chapter.

The internal fold (also called the velum, velar fold or mantle curtain) is the most conspicuous fold, consisting of a flap of tissue extending toward the pallial cavity at right angles to the shell in an undisturbed animal. In the dorsal-most anterior and posterior regions, this fold is progressively less developed toward its point of fusion at the hinge

Figure 3.2. Mucocytes and cilia on the pallial surface of *Placopecten magellanicus*. Figure 3.2.1–3.2.2: Left mantle lobe divided into 6 regions within which semiquantitative mucocyte counts were effected centripetally (a → c). 1 = few mucocytes, 2 = mucocytes easily distinguished but distinct, 3 = mucocyte abundance makes individual mucocytes barely distinguishable, 4 = mucocyte abundance makes individual cells indistinguishable. Only acid mucopolysaccharide-secreting (AMPS) mucocytes were observed, and no distinct pattern (and therefore no distinct rejection pathway) was reported (Beninger and St-Jean 1997). 3.2.3–3.2.4: Sparse, randomly-located tufts of long simple cilia (LSC) on the posterior (3.2.3) and anterior (3.2.4) pallial surface of the right mantle lobe, indicating lack of distinct rejection pathway (Beninger et al. 1999).

Figure 3.3. Diagram of a section through the mantle margin of *Placopecten magellanicus*, showing the secretion of the periostracum. Abbreviations: CO, cornea; CPN, circumpallial nerve; EPF, extrapallial fluid; IG, inner groove; LE, lens; MF, middle fold; ML, mineral layer; ON, optic nerves; OG, outer groove; PE, periostracum; PEG, periostracal groove; PPA, posterior pallial artery; R, retina; RPM, radial pallial muscles; SF1, primary shell fold; SF2, secondary shell fold; ST, sensory tentacles; V, velar fold. Modified after Drew (1906).

line. A row of guard tentacles is present on the inner-most margin of the velum in *Argopecten irradians* (Gutsell 1931) and in *Placopecten magellanicus* (Bourne 1964; Moir 1977a). The muscular velar fold plays an important role in water movement within the pallial cavity, notably during the swimming response, when it partially seals the pallial cavity, thereby directing jets of water which provide thrust. As the two valves close, the vela fold inward under the control of the parietovisceral ganglion and the radial pallial nerves, thus avoiding damage to the sensory structures of the mantle edge (Stephens 1978).

In the median dorsal region, the mantle is inserted into the ligament cartilage. There is no cardinal pallial crest (Ranson 1939) or pallial isthmus (Owen et al. 1953; Le Pennec 1978), and the hinge is almost totally reduced to the ligament. However, the cardinal region does show several long protuberances, which are in fact cardinal teeth or crura. The formation of the ligament and cardinal teeth is detailed in Chapters 1 and 2 of this volume.

The ligament is composed of two parts: the very prominent median internal cartilage or resilium resting upon a specialised shell formation called the resilifer, and a very fine external layer extending along the exterior dorsal shell margin. These two components of the ligament oppose an antagonistic force to that of the adductor muscle, so that in a relaxed state the two valves gape slightly, facilitating the circulation of water within the pallial cavity. Whereas in other bivalves the ligament is composed of calcium carbonate and a hydrated protein, in pectinids it is not calcified (Marsh et al. 1976). The rubbery consistency of the scallop ligament is more mechanically efficient than that of other bivalves, allowing the animal to swim and clear debris from the pallial cavity with a minimal energy cost (Trueman 1953). The ligament cartilage may be used to determine the age of individual scallops, as it often bears growth checks which are more distinct than those of the shell (Mottet 1979).

3.2.2 Microanatomy and Functions

Along the cardinal plate and in the regions where it adheres to the adductor muscle, digestive gland and pericardium, the mantle is simply composed of an internal epithelium and a thin subjacent conjunctive layer. In all other regions, the mantle is composed of three well-defined layers consisting of an internal and external epithelium separated by a thin layer of lacunar connective tissue. This middle layer is traversed by the pallial blood vessels, nerves, and muscles, which are particularly well-developed near the mantle margin.

Both the internal and the external epithelia rest upon a basal lamina composed of collagen fibres. The internal epithelium is composed of three cell types: columnar, microvilli-bearing cells, irregularly - distributed columnar cells bearing long ciliary tufts, and mucocytes. The secretions contained within the mucocytes are acid (high-viscosity) mucopolysaccharides. In contrast to those bivalves equipped with siphons and gill ventral particle grooves, neither the ciliary nor the mucocyte distributions present any pattern; this has been linked to the valve-clapping mode of pseudofeces evacuation from the pallial cavity (Beninger and St-Jean 1997; Beninger et al. 1999). It is likely that the radially

ventral particle transport previously depicted for the mantle surface of *Pecten maximus* (Orton 1912) is actually the result of the ventralward beat of the frontal cilia of the gill ordinary filaments as viewed in a half-shell preparation, since the patchy distribution of mantle cilia would not be effective in particle transport. The high viscosity of the mucocyte secretions, in the absence of other mucociliary transport adaptations, suggests that they facilitate the passage of water over the mantle surface, as has been suggested for other pallial surfaces in bivalves (Beninger et al. 1997a; Beninger and St-Jean 1997; Beninger and Dufour 2000; Dufour and Beninger 2001). The mantle cilia of *Placopecten magellanicus* probably do not contribute much to the flow of water in the pallial cavity, due to their sparse distribution (Beninger et al. 1999). Additional studies on other pectinid species would be most welcome.

The large pallial surface area of the mantle is greatly multiplied by the apical microvilli; together with the finely-branched blood vessels of the connective layer, this indicates that the mantle may be an important site for the exchange of gases and other dissolved molecules. Wandering amoebocytes and mantle epidermal cells are capable of absorbing particulate matter from the pallial cavity of several non-pectinid bivalves, and the ultrastructural characteristics of these cells indicate that they are capable of digesting such material (Bevelander and Nakahara 1966; Nakahara and Bevelander 1967; Machin 1977). As for the other surfaces of the pallial cavity, it is likely that direct exchange with the external medium may at least supplement the metabolic needs of the numerous epithelial cells.

We are unaware of data concerning the cell types of the external (shell side) epithelium in pectinids. In other bivalves, tall columnar cells presenting ultrastructural characteristics typical of translocation (e.g., apical microvilli and thick, convoluted basal lamina) have been observed (Neff 1972), and up to seven different cell types have been reported. Caecal cells extend mitochondria-rich processes into the shell itself, terminating on the outer shell surface (Reindel and Haszprunar 1996). This is clearly a very complex surface, which merits much further investigation.

Shell formation in bivalves generally follows two major steps: the cellular processes of ion transport and secretion of the organic matrix proteins; and the physico-chemical processes whereby calcium carbonate crystals are nucleated, oriented and assembled due to the presence of the organic matrix (for details, see Wilbur and Saleuddin 1983).

The detailed process of shell formation, and ontogenetic changes in shell microstructure and mineralogy, have been intensively studied by a number of workers in selected bivalve species (see reviews by Wilbur 1972, 1985; Crenshaw 1980; Wilbur and Saleuddin 1983; Watabe 1984), and for pectinids in particular (see Chapter 1 of this volume for review and references).

The shell is covered externally by a thin, fibrous organic layer called the periostracum, which may vary in thickness depending on the amount of mechanical abrasion and/or damage due to epizoots. The periostracum serves as a matrix for the deposition of the calcium carbonate crystals of the shell (Taylor and Kennedy 1969; Saleuddin and Petit 1983). The formation of the periostracum has been studied in detail in the freshwater bivalve *Amblema plicata perplicata* (Petit 1978) as well as in several marine species (Saleuddin and Petit 1983; Petit et al. 1988). Glandular cells located at the

base of the periostracal groove secrete the periostracal components, including quinone-tanned protein fibres (Petit 1978), polysaccharides and lipids (Brown 1952).

The outer edge of the shell fold contains numerous depressions, such that an extrapallial fluid is contained between the shell fold and the newly-formed periostracum (Fig. 3.3). Calcification is initiated at the small spicules of periostracum within this fluid-filled space, and progressively thickens (Wilbur and Saleuddin 1983). Extrapallial fluid may also be found in sub-periostracal depressions distributed within the shell. Mantle enzyme secretion has been studied in a number of bivalve species (Brown 1952; Waite and Wilbur 1976; Waite and Andersen 1978, 1980). Among the enzymes discovered, acid phosphatase and phenoloxidase are of particular interest. Acid phosphatase intervenes in the structural modification of the inner face of the periostracal layer (Chan and Saleuddin 1974), while phenoloxidase is involved in the tanning of the periostracal proteins (Bubel 1973a, b).

Between the outer (shell side) and inner (pallial side) epithelia, several cell types have been reported in non-pectinid bivalves: amoebocytes, porocytes/rhogocytes, nerve cells, haemocytes, gliointerstitial cells, as well as musculo-connective tissues (Reindl and Haszprunar 1996). Despite its deceptively simple gross appearance, the mantle is one of the most complex, multi-tasked organs in the Bivalvia.

3.3 PALLIAL ORGANS AND PARTICLE PROCESSING

The pectinid pallial organs are comprised of the mantle, gill, labial palps and lips. Studies to date have shown that, in pectinids, all of these structures save the mantle are involved in particle processing (Fig. 3.4), as outlined below. It is impossible to understand the mechanisms of particle processing without a good grasp of the underlying anatomy and micro-anatomy.

3.3.1 Gills

Much of the groundwork for bivalve gill anatomy was laid by Kellogg (1892, 1915), Janssens (1893), Ridewood (1903), Drew (1906), Setna (1930), and Atkins (1936; 1937a, b, c; 1938a, b, c; 1943). More recent studies on scallop gills in particular include the work of Owen and McCrae (1976), Morse et al. (1982), Reed-Miller and Greenberg (1982), Ciocco (1985), Beninger et al. (1988), Le Pennec et al. (1988), Beninger and Dufour (2000), and Dufour and Beninger (2001). Prior to the 1990's, function was largely inferred either from the possibilities afforded by the gill anatomy, by indirect means such as particle retention and clearance studies, or by observation of particle movement on opened animals. The resulting state of knowledge concerning particle processing mechanisms was eminently conjectural, and even an attempt to indicate the sizeable gaps and paradoxes concerning this subject in scallops was itself, in hindsight, somewhat naïve (although some of the conjectures were later borne out - Beninger 1991). From this point forward, an intense research effort was brought to bear on the problem, supplementing the existing techniques with tools specifically developed or adapted for the purpose: video endoscopy, mucocyte and cilia mapping, and confocal laser microscopy. The relevant

Figure 3.4. General organisation and function of the pallial organs involved in particle processing: gill (g), smooth (ss) or aboral surface, and ridged or oral surface of labial palps (lp), and upper (ul) and lower (ll) lips. Retained particles destined for further processing on the peribuccal organs are directed dorsally in the principal filament troughs (1), where they are incorporated into the anteriorward flow of mucus-particle slurry (ms) in the ciliated tracts of the gill arch and dorsal bend. Particles destined for rejection are directed ventrally in a viscous mucus on the ordinary filament plicae (2), where they are incorporated into mucus cords and masses of various length (mco), which are periodically expelled from the gill and pallial cavity (3) by valve adductions. Particles arriving from the dorsal ciliated tracts onto the labial palps (4) may continue along the oral groove (og), in a reduced-viscosity mucus, for ingestion (5) by the mouth (m). Particles rejected on the labial palps travel laterally in a viscous mucus within the troughs to the ventral margin (6), where they join pseudofeces moving posteriorly and are finally expelled from the postero-ventral tip (7). Modified from Beninger et al. (1990a).

studies concerning pectinids are, to date: Ward et al. 1991, 1993; Beninger et al. 1992, 1993, 1999; Beninger and St-Jean 1997a, b; Beninger and Dufour 2000; Dufour and Beninger 2001; Beninger et al. 2004). The following account of gill structure and function incorporates the information from all of these sources.

Adult scallops possess a heterorhabdic plicate gill, which means that the W-shaped left and right gills are composed of a series of two different types of filaments, suspended from the gill axis in a corrugated or plicate fashion. The principal filaments are situated in the troughs of the plicae, separated from each other by a variable number (11–20) of ordinary filaments (OF). The ascending branches of the filaments are approximately two-thirds the length of the descending branches (Figs. 3.5, 3.6.1).

The single reported exception to the heterorhabdic condition was the pectinid *Hemipecten forbesianus*, which was said to possess a homorhabdic gill (Yonge 1981). However, re-examination of the specimens studied by Yonge show unequivocally that the gill is heterorhabdic (Beninger, unpublished observations). There is thus no known exception to the rule of heterorhabdy in the pectinids.

Figure 3.5. General organisation and macro-anatomy of the gill. 1 - suprabranchial chamber, 2 - infrabranchial chamber, 3 - branchial nerve, 4 - afferent branchial vessel, 5 - efferent branchial vessel, 6 - gill arch, 7 - lateral wall of principal filament, 8 - ordinary filaments, 9 - descending branch of principal filament, 10 - dorsal expansion, 11 - afferent vessel, 12 - interconnecting vessel, 13 - efferent vessel in principal filament, 14 - ciliated spur (cilifer), 15 - ciliated disc, 16 - dorsal bend, 17 - ciliated tract, 18 - ascending filaments, 19 - interlamellar junction, 20 - ventral bend.

3.3.1.1 Gill axis and arch

A thin suspensory membrane joins the gill axis to the adductor muscle. Within the gill axis is situated, in a dorso-ventrally aligned sequence, the branchial nerve, the afferent branchial vessel, and the efferent branchial vessel (Figs. 3.5, 3.35.1). On either side of the gill axis is situated the eversible osphradial ridge (Sec. 3.8.2.4). Relatively abundant, but distinct ciliary tufts are found from the dorsal extremity of the gill axis to the osphradial ridge; below this feature, the axis is abundantly covered with simple cilia.

The gill arch comprises the fused and staggered proximal extremities of the principal and ordinary filaments. Here the afferent and efferent blood vessels of the principal filaments join with their counterparts in the gill axis and arch (Fig. 3.5). The ventral surface of the arch forms a ciliated groove which collects and transports particles arriving in a mucus slurry from the principal filaments (Fig. 3.4); the arch itself contains very few mucocytes (Beninger et al. 1992, 1993).

3.3.1.2 Principal filaments and dorsal expansion

Principal filaments differentiate well after metamorphosis, at a size of about 4 mm in *Pecten maximus*, and 3.3–5.0 mm in *Placopecten magellanicus* (Veniot et al. 2003). This represents a change in both gill structure and function, and therefore in particle processing mechanisms. It may thus be a critical stage, and potential indirect cause of mortality, in the early life of pectinids (Beninger et al. 1994).

The proximal third of the abfrontal surface of the principal filament presents a rather complex structure historically termed the ‘dorsal respiratory expansion’ (Setna 1930). No studies have yet been performed to evaluate its contribution to gas exchange, or any other role. We will refer to it here simply as the *dorsal expansion*. The dorsal expansion consists of an abfrontal afferent vessel, an efferent vessel contained within the wall of the PF, and a number of variously-shaped interconnecting vessels (Figs. 3.5, 3.6.1–3.6.3). The afferent vessel is covered with patchy but abundant simple cilia, whereas the efferent and interconnecting vessels bear only tufts of simple long cilia (Beninger et al. 1988; Dufour and Beninger 2001). The convoluted basal lamina of the shallow, one-cell-thick layer of the interconnecting vessels, together with their extensive, ramified apical microvilli (Fig. 3.6.4) strongly indicate a specialised role in translocation of dissolved substances between the external medium and the gill (Le Pennec et al. 1988). In addition to evaluating the extent of gas exchange, future studies should also examine dissolved organic substances, which are actively taken up by the mussel gill (Manahan et al. 1982; Wright et al. 1984; Wright 1987).

The principal filament displays a dynamic anatomical organisation, due to the periodic contractions of portions of its lateral walls - the ‘concertina’ response (Kellogg 1915; Setna 1930; Owen and McCrae 1976; Beninger et al. 1988, 1992). In the resting state, the filament comprises a ciliated frontal surface within a trough formed by the lateral walls (Fig. 3.6.3). The margins of the lateral walls bear ciliated spurs or cilifers (Kellogg 1892; Reed-Miller and Greenberg 1982), which are directed out and away from the PF (Figs. 3.5, 3.6.1–3.6.3). The inner surface of the cilifer is ciliated, and

Scanning electron micrograph of the interfilamentar junction (ifj) at ventral bend of an ordinary filament. Another ordinary filament (f) is attached behind. Note ciliated disc of interfilamentar junction, terminal cilia (tc) at ventral extremity, and absence of a particle groove. Figure 3.6.7. Thin section light micrograph of ordinary filaments. Rare abfrontal cilia (ac), lateral cilia (lc), latero-frontal (lfc) and frontal cilia (fc); supporting structures (st) and septum (s). Modified after Beninger et al. (1988) and Le Pennec et al. (1988).

interlocks with the cilia of similar spurs situated on the abfrontal surfaces of the ordinary filaments. The spurs of the ordinary filaments are ciliated on both sides, allowing adjacent filaments to adhere to each other at intervals along their lengths, thus preserving the structural integrity of the gill (Fig. 3.6.1). It appears that the orientation of the PF cilifers, which are ciliated on their inner side only, is responsible for the normal plicate arrangement of the gill filaments (Beninger et al. 1988). Contractions of the principal filament lateral walls modify the orientation of the cilifers, producing the concertina response, and is one of the mechanisms used to clear the gill and thus reduce ingestion volume when the stomach is full (Beninger et al. 1992, and section 3.3.1.5).

On the frontal surface of *Placopecten magellanicus*, the principal filament mucocytes contain a mixture of acid and neutral mucopolysaccharide secretions (Fig. 3.7), which would produce a mucus of relatively low viscosity, typical of enclosed or semi-enclosed transporting surfaces, which lead directly to other such surfaces, in bivalves (Beninger et al. 1993; Beninger and St-Jean 1997b).

3.3.1.3 Ordinary filament

The ordinary filaments have no dorsal expansions or lateral walls, and possess frontal, latero-frontal, and lateral ciliary tracts on their frontal surfaces (Figs. 3.6.5, 3.6.7). Contrary to many other bivalves, the scallop latero-frontal tract consists of only a single

Note association of acid mucopolysaccharide - secreting mucocytes with rejection function of ordinary filaments, mixed mucopolysaccharide -secreting mucocytes associated with transport of particles in semi-enclosed acceptance tracts of principal filaments. From Beninger et al. 1993.

row of cilia, which have been termed the pro-laterofrontal cilia (Owen and McCrae 1976). Rare cilia on the abfrontal surfaces are considered vestigial (Beninger et al. 1988; Beninger and Dufour 2000; Fig. 3.8), and it is interesting to contrast this with the dense abfrontal ciliation of the principal filaments. The presence of abundant cilia and mucocytes on the PF abfrontal surface (Fig. 3.8) has been related to the tardy evolutionary development of the PF's compared to the OF's; it has also been suggested that the mucocytes may play a role in preserving the structural integrity of the gill during valve adductions (Beninger and Dufour 2000).

The ordinary and principal filaments are organically joined only in the region of the dorsal bend (Morse et al. 1982; Le Pennec et al. 1988), which itself adheres to the mantle by means of interlocking cilia (Beninger et al. 1988). The ciliary connection to the mantle is easily broken when the gill retracts prior to valve adduction, or during a shunt response (Fig 3.9).

The ventral bend of each ordinary and principal filament bears a terminal ciliary tuft; the ventral bends are aligned via ciliary interfilamental junctions, forming a ciliated tract at the ventral bend, although there is no specialised trough (Fig. 3.6.6, 3.9.3). In addition, the ventral bends are imperfectly aligned along the dorso-ventral axis, such that this ciliated tract is in fact staggered (Beninger et al. 1988), probably aiding in the detachment of mucus-particle masses destined for rejection at this extremity.

Figure 3.8. Cilia and mucocyte distributions on abfrontal surface of *Placopecten magellanicus* gill. Figure 3.8.1. SEM of abfrontal surface, showing extremely sparse ciliation of ordinary filaments (OF), much greater ciliation of principal filament (PF) afferent vessel (AV). S, ciliated spur or cilifer. Figure 3.8.2. SEM detail of abfrontal surface of principal filament. Note dense ciliation of afferent vessel (AV), extremely sparse ciliation of lateral wall (LW). Figure 3.8.3. Relative position of *P. magellanicus* gill compared to other major gill types with respect to abfrontal cilia and mucocyte density. Note general tendency toward reduction of cilia on all ordinary filaments in more recent gill types. From Beninger and Dufour (2000) and Dufour and Beninger (2001).

The gill filaments gradually decrease in length toward the anterior and posterior extremities. In the anteriormost region of the gill this shortening of the filaments results in the convergence of the dorsal feeding tracts with the oral groove at the base of each pair of labial palps (Fig. 3.4).

3.3.1.4 Haemolymph circulation in the gill

The gill filaments are essentially hollow tubes within which the haemolymph circulates. The internal walls of the filaments are strengthened by collagenous supporting structures (Fig. 3.6.7), which appear to be more numerous in the region of the ventral bend (Le Pennec et al. 1988). Blood enters the afferent vessel of the dorsal expansion, flows down the principal filament lumen and enters the organic junction between filaments in the dorsal bend. It then flows down the ordinary and principal filament lumina and rises dorsally to join the efferent vessel of the principal filament, which empties into the efferent branchial vessel (Morse et al. 1982). The lack of a distinct anatomical separation between afferent and efferent blood in the lumina of the filaments indicates that mixing of haemolymph probably occurs.

3.3.1.5 Particle processing on the gill

Owen (1978) originally proposed a non-‘filter’-feeding mode of particle capture for several bivalve families, including the Pectinidae. In these species, the plical arrangement of the relaxed gill results in particle-laden water currents being directed toward the densely-ciliated troughs of the principal filaments and dorsally. Detailed *in vivo* endoscopic observations of the gills of *Placopecten magellanicus* and *Pecten maximus* support this proposed mechanism (Beninger et al. 1992; Beninger et al. 2004), but the microscopic events are not yet known. It is clear that the principal filaments send particles destined for secondary processing by the peribuccal organs dorsally to the gill arch and dorsal bend. A reduced-viscosity mucus accompanies these particles (Beninger et al. 1992; Fig. 3.7).

The ordinary filament plicae possess ventralward-beating frontal cilia, which direct mucus-particle masses to the ventral bend; this is probably accomplished by the phylogenetically ubiquitous mechanism of mucociliary transport, as has been recently documented *in vitro* for *Mytilus edulis* (Beninger et al. 1997b). These masses are characterised by a high-viscosity mucus, in keeping with the exposed surface and predominantly counter-current water flow (Beninger et al. 1992, 1993; Beninger and St-Jean 1997b). Most of these masses are rejected from the ventral bend, and exit the pallial cavity via valve adductions (Kellogg 1915; Owen and McCrae 1976; Beninger et al. 1992, 1999; Fig. 3.9).

3.3.1.6 Particle selection at the gill

As explained above, particles sent dorsally in the principal filament tracts are more likely to be ingested, whereas those sent ventrally are more likely to be rejected. It is

Figure 3.9. Ingestion volume regulation and pseudofeces formation on the *P. magellanicus* gill. Figure 3.9.1. Diagram showing dorsal bend in normal feeding position applied to the mantle surface (M). Solid arrows show direction of particle-laden water currents in infrabranchial cavity, open arrows show passage of particle-depleted water through the interfilamentar spaces. Figure 3.9.2. Dorsal bend detached from mantle surface, allowing particle-laden water to exit directly into the suprabranchial cavity. Figure 3.9.3. Video endoscopic micrograph showing mucus-particle mass detaching from ventral bend (solid arrow). Open arrow indicates anteriorward direction of pseudofeces movement along the ventral bend. From Beninger et al. (1992).

tempting to invoke a selective process for such a system, as has been suggested for the heterorhabdic gill in general (Atkins 1937a; Beninger and St-Jean 1997a), and the pseudolamellibranch oyster gill in particular (Ward et al. 1998); this would furnish a satisfying explanation of the heterorhabdic condition. This question was settled by presenting known mixtures of intact and empty diatoms (*Coscinodiscus perforatus*) and *in vivo* sampling of the dorsal and ventral gill tracts, as well as palp pseudofeces, combined with microscopic determinations of particle proportions at each sampling site (Beninger et al. 2004). Qualitative particle selection was indeed demonstrated on the gill, and a second level of particle selection was also found at the labial palps. The organic casing and associated organic molecules of this diatom appear to constitute a key quality cue for *Pecten maximus* (Beninger and Decottignies, in press).

In contrast to the oyster gill, the width of the scallop principal filament trough (approx. 200 μm in *Placopecten magellanicus* and *Pecten maximus*), as well as its relative plasticity, allows the admission of most suspended particles (no doubt accounting for the presence of some very large particles in the stomachs of scallops (Mikulich and Tsikhon-Lukanina 1981; Shumway et al. 1987)). The upper size constraint on the qualitative selection of particles at the scallop gill is thus much larger than that of the other major heterorhabdic gill type, the pseudolamellibranch gill of the oyster (Cognie et al. 2003). At this point, however, the detectors, effectors, and microscopic sequence of events involved in qualitative selection are totally unknown.

3.3.1.7 Particle retention lower size limit

The lower size limit for the efficient retention of natural particles in scallops is approximately 5 μm . Clearance studies indicate that pectinids, which possess only a single row of simple latero-frontal cilia, have a low retention efficiency for particles less than 5–7 μm in diameter, in contrast to the majority of bivalves, which possess well-developed, compound latero-frontal cilia called *cirri* (Møhlenberg and Riisgard 1978; Riisgard 1988). It is difficult to make direct comparisons, however, since the vast majority of bivalves possessing cirri also have a homorhabdic gill. The oyster (Fam. Ostreidae) is an interesting oddity in the bivalve world. Kellogg (1892) called it a 'very degenerate form', which however possesses the most complex of gill types, with both latero-frontal cirri (albeit reduced in size) on its ordinary filaments, a heterorhabdic gill, and a ventral particle groove. Much is still to be learned concerning gill function in this unique group.

3.3.1.8 Ingestion volume regulation on the gill

Five different mechanisms of ingestion volume regulation have been identified in the functioning scallop gill (Beninger et al. 1992): rejection of particles from the principal filament troughs onto the ordinary filament plicae, arrest of the anteriorward dorsal feeding currents, reduction of input from the principal filaments to the dorsal tracts, detachment of the dorsal bends from the mantle, allowing a flow-through shunt (Figs. 3.9.1, 3.9.2), and the concertina response described above. The variety of such

mechanisms indicate that this is an important process in scallops, particularly under high seston concentrations, and also that the scallop is probably able to fine-tune ingestion volume using a combination of these mechanisms.

3.3.2 Labial Palps and Lips

In addition to the paired labial palps found in all bivalves, pectinids possess a complex, ramified pair of lips covering the mouth. While considerable progress has been made in the understanding of their roles in particle processing, the extreme sensitivity of the scallop peribuccal structures to any local mechanical disturbances has rendered direct observation of particle processing impossible to date.

3.3.2.1 Labial palps

The labial palps of scallops are similar to those of the majority of bivalves, consisting of a right and left pair of tissue flaps, into which the anterior ends of the gills are inserted (Fig. 3.4). The detailed structure and ultrastructure of scallop labial palps has been reported for only two species, *Placopecten magellanicus* and *Chlamys varia* (Beninger et al. 1990 a). The two surfaces facing the gill consist of a ciliated epithelium organised into a series of troughs and ridges oriented at right angles to the gill axis (Figs. 3.4, 3.10.3). Each ridge consists of an anterior fold, a crest, and a posterior fold (Figs. 3.10.2, 3.11.3). At the base of the inner surfaces is a ciliated oral groove leading anteriorly to the mouth (Figs. 3.4, 3.11.1). The “smooth” outer or aboral surfaces of the palps possess tufts of cilia, which appear too sparse to be involved in mucociliary transport. The aboral surface is rich in mucocytes, however, probably facilitating the passage of pallial currents (Fig. 3.10.1). Between the inner and outer epithelia is a haemolymph sinus, within which numerous haemocytes may be observed, traversed by lacunar muscular-connective tissue (Figs. 3.10.1, 3.10.2).

The basal lamina of the labial palp oral surface is thick, complex, folded, and presents numerous indentations (Fig. 3.10.4). Together with the highly-branched microvilli and the observation of lysosomes in the apical region, these observations suggest that the palp oral surface is involved in absorption, although this requires much further study (Beninger et al. 1990a).

3.3.2.2 Particle processing on the labial palps

Pseudofeces are voided from both the labial palps and gill in the same manner, i.e., by valve adduction; it is thus difficult to determine the exact origin of the various pseudofeces masses. *In vivo* sampling (as in Beninger et al. 2004) allows us to at least sample pseudofeces observed to be rejected by the postero-ventral palp extremity (see below), so it is possible to affirm that the palps constitute a second site of qualitative particle selection. We do not yet know what the relative contributions of the gills and labial palps are to ingestion volume regulation and qualitative selection, and this is likely to be a very complex matter of investigation. Both of these processes involve rejection

and acceptance, however, and mucocyte mapping data shed some light on the underlying mechanisms of each.

Figure 3.10. Labial palps of *Placopecten magellanicus*. Figure 3.10.1. Transverse histological section of palp margin. Note flattening of crests at the approach to the flat margin, and mucus-particle mass of pseudofeces (mp) at margin edge. Arrowheads indicate numerous narrow mucocytes on oral surface (os), goblet-cell type mucocytes on aboral surface (as). c, cilia; hs, haemolymphatic sinus. Modified Masson trichrome. Figure 3.10.2. Transverse histological section in mid-region of palp, showing structure of ridges and troughs. af, anterior fold; bl, basal lamina; c, cilia; cr, crest; mct, lacunar muscular-connective-tissue; pf, posterior fold; t, trough (rejection tract). Modified Masson trichrome. Figure 3.10.3. SEM of densely-ciliated palp oral surface, mid-region. cr, crest; mp, mucus-particle masses; pf, posterior fold. Figure 3.10.4. TEM detail of basal region of oral surface epithelium, showing part of elongated mucocyte (mc); ciliated and non-ciliated epithelial cells have indented basal membranes (arrowed); all cells rest upon multi-layered, irregular basal lamina (bl). From Beninger et al. (1990a).

Figure 3.11. Mucocyte types and distribution on labial palps of *Placopecten magellanicus*. Figure 3.11.1. Labial palp mucocyte types and density throughout the oral groove (OG, means + standard deviations). Note dominance of lower-viscosity mixed secretions in this semi-enclosed surface. Bold arrow denotes arrival of mucus slurry from gill arch, hollow arrow shows rejection pathway from ventral margin. Figure 3.11.2. Labial palp mucocyte types and densities (means + standard deviations) on anterior (A) and posterior (P) ventral margin, on unreflected surface (UR) and reflected surface (R). Note absence of acid mucopolysaccharide-secreting mucocytes on reflected surface, facilitating discharge of pseudofeces. Figure 3.11.3. Mucocyte types and densities (means + standard deviations) on representative crest of palp oral surface (postero-dorsal region). Note dominance of acid mucopolysaccharides in trough (t), which is a semi-enclosed surface leading directly to the exposed surface of the palp ventral margin. Note also dominance of reduced-viscosity mucopolysaccharide-secreting mucocytes on crest summit (s), allowing extraction of particles from mucus for sorting. af, anterior fold; pf, posterior fold. From Beninger and St-Jean (1997a).

Particles destined for ingestion are accompanied in the oral groove by a medium-viscosity mucopolysaccharide (MPS), in keeping with the semi-enclosed nature of the transporting surfaces (Beninger and St-Jean 1997a, b; Fig. 3.11.1). Particles entering the palp troughs of several non-pectinid species have been observed via endoscopy to be destined for rejection, and this agrees with observations performed on dissected, live specimens of *Placopecten magellanicus* (Beninger and St-Jean 1997a; Beninger et al. 1997a). Particles destined for rejection are accompanied by acid (viscous) MPS in the palp troughs, to the lateral (ventral) margins which are also rich in acid MPS (Beninger and St-Jean 1997a; Figs. 3.11.2, 3.11.3), conforming to the rule of mucociliary transport on surfaces which are themselves exposed and subjected to a countercurrent water flow, or on surfaces which lead directly to same (Beninger and St-Jean 1997b). At the posterior-most tip of the palp ventral margin, the mucocyte viscosity again decreases; this probably assists in the release of the pseudofeces; Fig. 3.10.1), following which they are expelled from the pallial cavity by valve adduction (Beninger et al. 1999).

3.3.2.3 Lips

Despite their strategic position and visibly complex anatomy, the lips of pectinids have received relatively little attention. Drew (1906) described them briefly as ramifications of the labial palps, while Dakin (1909) also gave a summary account of these structures, suggesting that the ramified margins allow the lips to form a hood over the oral groove. Some observations of the lips of *Pecten maximus* were made by Gilmour (1964, 1974), although photomicrographs of these observations were largely lacking. Detailed structural and ultrastructural observations are only available for *Placopecten magellanicus* and *Chlamys varia* (Beninger et al. 1990b).

The lips arise as ramifications of the anterior margins of the paired labial palps (Fig. 3.4). Their dendritic configuration completely covers the mouth; upon separation they may be seen to comprise an upper and a lower lip (Fig. 3.4, 3.12.1). The cauliflower-like branches possess two distinct surfaces: a ciliated oral epithelium, and a non-ciliated aboral epithelium (Figs. 3.12.2–3.12.4). Both of these epithelia terminate in a covering of apical microvilli. Whereas the mucus secretion of the aboral surface probably facilitates the passage of pallial currents over this complex surface, the types and distribution of mucocytes on the oral surface presents a very definite gradient (Fig. 3.12.1), with a large number of acid-dominant MPS-secreting mucocytes close to the mouth, and a smaller number of acid and acid-dominant MPS - secreting mucocytes in the mid-region of the lips. It has been suggested that these characteristics function to prevent the removal of food particles destined for ingestion when the scallop initiates its frequent valve adductions for pseudofeces clearance (Beninger and St-Jean 1997b).

The internal structure of the lips consists of a haemolymphatic sinus containing numerous haemocytes, traversed by a lacunar muscular - connective tissue. Muscle fibres attached to the basal lamina are responsible for the rapid contraction observed in response to the slightest mechanical disturbance in the vicinity of the lips (Fig. 3.13.2). It may be presumed that the extension of the lips is accomplished via a forced flow of haemolymph into the lacunar connective tissue.

Figure 3.12. Lips of *Placopecten magellanicus*. Figure 3.12.1. Mucocyte types and distribution on the lips of *Placopecten magellanicus*. Mean counts $\pm$ standard deviation for epithelial mucocytes in three counting zones: D, distal; M, median; P, proximal to mouth (m). Note dominance of acid and acid-dominant mucopolysaccharide-secreting mucocytes in median region, facilitating trapping of particles dislodged from oral groove (see text). Standard deviation for proximal zone negligible. log, left oral groove. Figure 3.12.2. Semithin section of lips, showing ciliated (c) crests (cr) and intermediate sparsely-ciliated epithelium of oral surface (soe), and sparsely-ciliated aboral epithelium (sae). Figure 3.12.3. SEM of ciliated crest, showing dense ciliation and wave beat pattern. Figure 3.12.4. SEM of transition from ciliated epithelium of crest (cr, oral surface) to sparsely-ciliated epithelium of aboral surface (sae). Arrows indicate surface openings of mucocytes. From Beninger et al. (1990b).

As was observed for the scallop labial palps, the lip oral epithelium presents highly - branched apical microvilli, and a thick, greatly-indented basal lamina (Figs. 3.13.1, 3.13.2), suggestive of absorption and transport of dissolved or colloidal substances to the underlying haemolympathic sinuses.

Figure 3.13. TEM details of *Placopecten magellanicus* lip, ciliated crest of oral surface. Figure 3.13.1. Apical region of epithelium. Note branched microvilli (mv) and phagosomes (p), indicating absorption of material from the epithelial surface. Ciliary roots (rc) extend beyond apical mitochondria (m) to the region of the nucleus (n). c, cilia. Figure 3.13.2. Basal region of epithelium. Note thick, multi-layered basal lamina (bl), with long indentations (arrows), indicative of transport to the underlying haemolymphatic sinus. h, haemocyte; mf, muscle fibre responsible for lip contraction.

3.4 DIGESTIVE SYSTEM AND DIGESTION

The scallop digestive system consists of the mouth, oesophagus, stomach and crystalline style, digestive gland and intestine. Its anatomy and function are similar to that of other bivalves (see Purchon 1977 and Morton 1983 for review), with several primitive features which are outlined below.

3.4.1 Mouth and Oesophagus

Particles and associated mucus enter the mouth from the oral groove at the base of the labial palps. The mouth is a simple ciliated opening to the narrow, ciliated oesophagus. The oesophageal epithelium is plicate, allowing accommodation, which may account for the presence of comparatively large food particles in the stomach (Mikulich and Tsikhon-Lukanina 1981; Shumway et al. 1987). Both the buccal and oesophageal epithelia are mucociliary, with a dominance of acid MPS-bearing mucocytes in the peribuccal region, and a mixture of acid and neutral MPS mucocytes in the oesophagus, as is the rule for exposed and enclosed mucociliary surfaces, respectively, in bivalves (Beninger et al. 1991; Beninger and St-Jean 1997b). The beating cilia of the mouth and oesophagus assist in transporting the relatively low-viscosity mucus - particle masses toward the stomach (Beninger and St-Jean 1997b). Apart from the epithelial mucocytes, no glands are present in the scallop oesophagus (in contrast to the 'salivary glands' found in other molluscs, including *Mytilus edulis* - Beninger and Le Pennec 1993).

The pectinid alimentary canal is characterised by a pseudostratified, microvillous-bearing epithelium with a dominance of tall, narrow, ciliated cells, interspersed with acid and neutral MPS - containing mucocytes (Figs. 3.14, 3.18), as well as non-ciliated absorptive cells. The epithelium rests upon a thick basal lamina, surrounded by a thick layer of connective tissue, occasionally traversed by strands of smooth muscle (Beninger et al. 1991; Le Pennec et al. 1991; and Fig. 3.18.4).

3.4.2 Stomach, Crystalline Style, and Gastric Shield

A detailed description of the pectinid stomach may be found in Purchon (1957). According to his system of classification, scallops possess a type IV stomach with the following salient features:

The oesophagus enters the stomach anteriorly and somewhat dorsally. The stomach is roughly oval in shape, with irregular folds and depressions delimiting different regions. A crystalline style projects across the stomach and into a well-developed dorsal hood, which is situated just above the gastric shield. The style originates in the style-sac, which is conjoined to the intestine in the Pectinidae. Depending on its degree of development, the style may occupy most of the lumen of the descending loop of the intestine. The historic term "crystalline style" is a misleading one, since the style is not crystalline, and it may only be presumed that the adjective refers to its translucent, pale coloration.

The exact composition of the crystalline style is not yet known, although it must be a stabilised mucopolysaccharide-type structure. Using very rudimentary methods, Dakin

Figure 3.14. Structure and ultrastructure of the oesophagus in *Pecten maximus* and *Placopecten magellanicus*. Figure 3.14.1. Histological section of *Pecten maximus* oesophagus. Cilia (c) of ciliated pseudostratified epithelium, containing mucocytes (mc), beneath which are found a basal lamina (l), a smooth muscle layer (sm) and the digestive gland (dg). Note mucus-particle masses (mp) at the entry to the oesophagus, and folds (f) which allow ingestion of particles larger than the oesophageal diameter. PAS - alcian blue stain. Figure 3.14.2. Histological section of *Placopecten magellanicus* oesophagus. General structure as in Fig. 3.14.1, but note terminal bulbs (tb) of mucocytes, characteristic of this species. Abundant mucus (mu) is visible in the oesophagus, histochemically similar to that contained in the mucocytes. PAS-alcian blue stain. Figure 3.14.3. Transmission electron micrograph of the ciliated epithelium of the *Pecten maximus* oesophagus. Note the numerous mitochondria (m) at the bases of the cilia (c). The apical surface is covered with microvilli (mv).

(1909) detected unspecified proteinaceous substances in the style of *Pecten* sp. In a more modern study of the styles of twelve bivalve species, including *Pecten novaezelandiae*, Judd (1987) concluded that the crystalline style is probably composed of mucin type glycoproteins rather than glycosaminoglycans. The viscosity of these glycoproteins, or acid mucopolysaccharides, varies considerably among individuals and conditions,

probably as a result of varying gut pH (Mathers and Colins 1979); in any event, the crystalline style can appear to be quite well-defined (but very easily broken or sectioned), or very poorly-defined (rather syrupy). It is presumably secreted by the walls of the style sac (Dakin 1909; Mathers 1976).

The gastric shield is situated at the head of the crystalline style. It covers the stomach epithelium, and is easily visualised in histological sections with either Fast Green or Alcian Blue. Shaw and Battle (1958) presented strong evidence that the oyster gastric shield may be composed of chitin (*N*-acetyl-D-glucosamine), and this has henceforth been supposed to be the case for bivalves in general (Morse and Zardus 1997). Chitin does not seem to be present anywhere else in the Bivalvia, so its presence in the gastric shield is intriguing. Obviously, the mechanical properties of chitin make it suitable for the grinding function it appears to perform (see below), and it may be that no other non-mineralised substance could perform such a task effectively. Although it contains other digestive enzymes (see below), the crystalline style does not appear to contain chitinases (Wojtowicz 1972); this is understandable, given the chitin composition of the gastric shield (Shaw and Battle 1958).

Although it was long assumed that one of the functions of the crystalline style was to drag mucus-particle 'strings' into the stomach (e.g., Purchon 1977), mucociliary transport via the ciliated epithelium of the oesophagus seems a much more plausible mechanism; moreover, as described above, particles appear to be ingested in a reduced-viscosity mucus, which would not lend itself to a 'capestan' model. However, the style rotation, effected by the co-ordinated ciliary beat of the stomach and intestinal epithelia, accomplishes two important functions: (1) it triturates the particles against the gastric shield, situated at the head of the style, and (2) it stirs the stomach contents, placing them in contact with plicate ciliary sorting areas located on the inner wall of the stomach (Purchon 1977). The crystalline style also undergoes periodic partial dissolution, liberating enzymes, which participate in extra-cellular digestion. In a study of *Placopecten magellanicus*, Wojtowicz (1972) identified relatively high α -amylase and laminarinase activity from the crystalline style. These enzymes originate in the style sac; they are incorporated into the style as it is secreted.

A cycle of dissolution - reconstitution of the crystalline style has been observed in both *Pecten maximus* and *Chlamys varia* subjected to diurnal changes in current flow (Fig. 3.15); this cycle has been attributed to variations in the pH of the style sac resulting from rhythmic activity in the digestive gland. This rhythmic activity in *P. maximus* and other nearshore bivalves appears to correspond to distinct feeding cycles as a function of the tides (Langton and Gabbott 1974; Mathers 1976; Mathers and Colins 1979).

The discovery of bacteriolytic activity in bacteria associated with the crystalline style of *Mytilus edulis* (Seiderer et al. 1987) raises the possibility that some extracellular digestion of bacteria occurs in the stomachs of bivalves. Such studies should be extended to the Pectinidae.

Figure 3.15. Diagrammatic illustration indicating the correlation of tidal cycle over a 12-h period with the cycles of feeding, extracellular digestion, and diphasic intracellular digestion in the tubules of a single individual of *Pecten maximus*. From Mathers (1976).

3.4.3 The Digestive Gland

To date, the terminology of the architecture of the digestive gland has been based on reconstructions of histological sections. Principal ducts from the gland open laterally into the plicated sorting regions of the stomach (two ducts in *Chlamys opercularis* and four in *Pecten maximus* - Purchon 1957). The principal ducts branch into secondary ducts, and finally into blind digestive 'tubules'. Recent studies using injected resin molds, however, show that the secondary ducts of *Pecten maximus* terminate in a short tubular region, followed by an acinus rather than a tubule (Le Pennec 2000 and Figs. 3.16.1, 3.16.2).

The probable mechanism of particle entry into the ducts and acini has been described by Owen (1955). Although the stomach and principal duct cilia create currents directed away from the principal ducts, a compensating current is created due to the distribution of cilia on only one side of the principal ducts (such a current was later demonstrated in *Ostrea edulis* by Mathers 1972). The movement of fluids into the non-ciliated secondary ducts and the acini is accomplished by aspiration, replacing the fluids absorbed by the digestive cells of the tubules. The weak current allows only the finest suspended particles to reach the acini (Owen 1955); larger particles are presumably digested in the stomach and intestine (see below).

The exact nature and number of different cell types in the bivalve digestive acini has been the object of considerable debate (see review by Morton 1983 and Weinstein 1995 for recent references). Although immature digestive cells are usually reported to be present in depressions or "cypts" of the acini (e.g., Henry et al. 1991), such cypts do not appear to be a constant feature in *Pecten maximus* (Henry et al. 1991; Le Pennec et al. 2001; and Fig. 3.16.3). Whether found in cypts or between and below the acinal cells, the immature cells are probably undifferentiated precursors for all of the other cell types observed in the tubule. The immature cells pass through a transient flagellated stage (Fig. 3.17.3), after which they differentiate either into absorptive (digestive) cells or secretory cells. The mature absorptive cells pinocytose particulate matter, which is digested within vacuoles called digestive spherules (Fig. 3.17.5). In *Pecten maximus*, the end product of this digestion appears as "residual bodies" (Mathers 1976 and Fig. 3.17.6). The absorptive cells eventually rupture, entraining the degeneration of the acinus (Mathers 1976; Mathers and Collins 1979), and the wastes are swept toward the stomach and ultimately the intestine. Acini are regenerated by immature cells.

The mature secretory cells possess an electron-dense cytoplasm rich in rough endoplasmic reticulum and Golgi bodies (Figs. 3.17.2, 3.17.4). These structures probably secrete digestive enzymes. Precise localisation of the enzymes is difficult, since cell type cannot be readily deduced from histochemical preparations. Whereas secretory cells would primarily secrete enzymes into the acinal lumen for extracellular digestion, intracellular digestion would be continued using the enzymatic equipment within the absorptive cells. A wide range of enzymes has been identified within the digestive gland (both the acini and the digestive ducts) of *Placopecten magellanicus* (Wojtowicz 1972), *Argopecten irradians* (Brock et al. 1986), and *Pecten maximus* (Henry et al. 1991), notably those involved in carbohydrate and peptide digestion. The absence of proteases (Henry et al. 1991) suggests that initial protein digestion occurs in the stomach.

Figure 3.16. Topology and histology of the digestive gland in *Pecten maximus*. Figure 3.16.1. Internal mold of digestive gland, showing three-dimensional structure and anatomical relationships of point of attachment to stomach (s), principal duct (pd), and secondary duct (sd). Figure 3.16.2. Detail of internal mold, showing ramification of secondary duct (sd) from principal duct (pd), the short tubular zone (tz), terminating in the digestive acinus (da). Figure 3.16.3. Histological section of tubular and acinal regions in the Bay of Brest in April. Note large lumen (l), and few adipocyte-like digestive cells (a). Figure 3.16.4. Same type of section as in Fig. 3.16.3, but from a specimen sampled in the Bay of Brest in December. Note virtual absence of lumina and abundance of adipocyte-like digestive cells (a) in the digestive acini. Micrographs courtesy of G. Le Pennec, Université de Bretagne Occidentale.

Chitinase (N-acetylglucosaminase) is abundant in the digestive gland of *Pecten maximus*, however (Henry et al. 1991), and this probably enables scallops to utilise the energy-rich chitin contained in some diatom frustules (McLachlan et al. 1965; Jeuniaux 1982, as well as in the crustacean exoskeletons which may be abundant in bivalve stomachs, including those of pectinids (Shumway et al. 1987; Davenport and Lehane 2000; Lehane and Davenport 2002). Restriction of chitinases to the digestive gland (and intestine, see sections 3.4.4 and 3.4.5) may be sufficient to protect the gastric shield.

Figure 3.17. Transmission electron micrographs of digestive gland ultrastructure in *Pecten maximus*. Figure 3.17.1. Low-power micrograph showing general aspect of digestive (dc) and secretory (sc) cells. Arrows indicate rough endoplasmic reticulum in secretory cells. n, nucleus; nu, nucleolus. Figure 3.17.2. Detail of secretory cell, showing mitochondria (m) and rough endoplasmic reticulum (rer). Figure 3.17.3. Transmission electron micrograph of the apical region of a young secretory cell (sc) in the digestive gland. Note the presence of flagella (f). Figure 3.17.4. Transmission electron micrograph of the basal region of a mature secretory cell. Note the numerous vacuoles (v), extensive rough endoplasmic reticulum (rer), and the characteristic annular Golgi apparatus (G). Figure 3.17.5. Transmission electron micrograph of the basal region of an absorptive cell. Numerous residual bodies (rb) and lipid granules (lg) are present. Note the thick basal lamina (bl). Micrographs courtesy of A. Donval and G. Le Pennec, Université de Bretagne Occidentale, Brest, France.

Distinct digestive phases have been identified in several bivalve species (Morton 1977; Robinson and Langton 1980; Robinson et al. 1981), including *Pecten maximus* and *Aequipecten opercularis* (Mathers 1976, Mathers and Collins 1979). These phases are cyclic and linked to environmental factors such as the tidal cycle (Fig. 3.15), and may be somewhat complex, as in the case of *A. opercularis*, which displays co-dominant diphasic cycles as a function of tidal rhythm.

In addition to cyclicity on short time scales such as the tidal cycle, recent investigations have shown that ultrastructural characteristics of the digestive gland cells in *Pecten maximus* present long-term changes over the course of a year, notably with respect to the amount of lipid present in digestive cells within the acinus, which may resemble adipocytes at certain periods of the year (Le Pennec et al. 2001). The digestive cells of the tubular region store smaller lipid droplets, and these two types of lipid reserves are used differentially; it has been proposed that the lipid droplets of the tubular digestive cells are used for maintenance energy reserves, whereas those of the acinus are used for acute demand states such as gametogenesis (Le Pennec et al. 2001; Figs. 3.16.3, 3.16.4). Long-term variations in digestive gland lipid contents have also been observed in *Pecten maximus* using biochemical analyses (Strohmeier et al. 2000).

The pronounced endocytotic character of the digestive gland may account for the prevalence of prokaryotic infections of this organ by *Chlamidia*-like organisms (Morrison and Shum 1982).

3.4.4 Intestine, Rectum, and Anus

The remainder of the pectinid alimentary canal may be divided into three regions of similar length: the descending and ascending portions of the intestine, and the rectum. The descending portion of the intestine leaves the stomach mid-ventrally, passes through the digestive gland and into the gonad. In *Pecten maximus* and *Placopecten magellanicus*, the intestine continues almost to the distal extremity of the gonad before looping back, whereas in *Chlamys opercularis* the intestine curves back at about the level of the junction between the ovarian and seminal portions of the gonad. The ascending limb then returns through the digestive gland to follow the course previously described (Section 3.1).

The cell types, which form the intestine, are similar to those described for the alimentary canal in general. In the portion, which is exposed to the pallial cavity, a thin outer epithelium surrounds and protects the intestinal epithelium (Fig. 3.18.2). Although several studies of the anatomy and histology of the intestine have been performed on non-pectinid bivalves (see Morton 1983 for review), we are only aware of scattered information for a scallop species (*Pecten maximus* - Le Pennec et al. 1991a,b; Beninger et al. 2003). The intestinal epithelium consists of cells with apical microvilli and cilia, resting on a thick basal lamina (Figs. 3.18.1, 3.25). The underlying tissue is muscular-connective (Figs. 3.18.2, 3.18.4). Numerous mitochondria are present, and decomposing dead cells are frequently observed (Figs. 3.18.3–3.18.4). The intestinal cells themselves contain numerous enzymes: non-specific esterases, alkaline and acid phosphatases, chitinase, and leucine aminopeptidase (Le Pennec et al. 1991a).

Figure 3.18. Histology, ultrastructure, and assimilation in the intestine of *Pecten maximus*. Figure 3.18.1. Portion of intestine passing through gonad. The intestinal epithelium (ie) is composed of tall, thin, pseudostratified, mainly ciliated (c) cells, resting on a thick basal lamina (bl) and surrounded by connective tissue (ct). Ferritin (f) injected into the intestinal lumen has been readily assimilated by the cells. The alimentary tract was allowed to purge for 48 h prior to injection. Prussian blue - nuclear red stain. Figure 3.18.2. Portion of intestine exposed to the pallial cavity (pc). Note thin outer epithelium (oe) surrounding intestinal epithelium (ie). Clear spaces (arrows) indicate acid mucopolysaccharide-secreting mucocytes. am, adductor muscle; b, bolus. Masson trichrome stain. Figure 3.18.3 Transmission electron micrograph of the apical region of intestinal epithelium cells. The intestinal cells (ic) bear cilia (c) and microvilli (mv). The numerous mitochondria (m) are dilated due to hypotonic fixation. Dead cells (dc) are frequently observed. Figure 3.18.4. Transmission electron micrograph of the basal region of the intestinal cells (ic). Note the thick basal lamina (bl), and the muscle fibres (mf) in the muscular-connective tissue (mct). Dead cells (dc) are again present. Micrographs courtesy of A. Donval, Université de Bretagne Occidentale, Brest, France.

The cellular structure of the rectum has been studied in *Patinopecten yessoensis*. This region consists mainly of ciliated cells, with few mucus cells. Some solitary cells of apparently neuroendocrine origin have also been observed, but their function has not been determined (Usheva 1983).

The scallop digestive system terminates in an anus, which is curved dorsally and away from the adductor muscle, such that the feces are voided in the excurrent water flow (Drew 1906). The anus is surmounted by a prominent lip (Dakin 1909), which in *Placopecten magellanicus* may function as a sphincter (P.G. Beninger, personal observations).

3.4.5 Digestive Sites and Postingestive Selection

As has been reported for some decades in various bivalves, the digestive gland is not the only site of extra- and intracellular digestion in bivalves. The intestine is also active in both types of digestion (Zacks 1955; Mathers 1973a,b; Stewart and Bamford 1976; Le Pennec et al. 1991a,b; Beninger et al. 2003; Fig. 3.18.1), and cannot simply be considered as a conduit for wastes and particles 'rejected' from the stomach and digestive gland (Brillant and MacDonald 2000). Indeed, as detailed in section 5, transfer of material from the intestine to developing oocytes suggests that in scallops the gonad intestinal loop may be an important site of both digestion and metabolite transfer to the gonad. As the majority of the intestine passes through the gonad and digestive gland, it is thus not possible to conclude that material therein is necessarily indigestible or that it has been 'rejected' following ingestion. While it is thus not evident what physiological significance may be attributed to the difference in location of digestion, it is clear that the presence of a given particle or fragment in the intestine does not signify that it will not be or has not been at least partially assimilated. Whereas the routing of particles to the digestive gland or to the intestine for eventual digestion indicates a difference in treatment, and hence a form of post-ingestive sorting, we do not know whether this reflects a difference in the percentage of each particle type assimilated by the digestive system. Rather, significantly different gut retention times may simply indicate that less nutritious particles spend less time in the digestive system (Brillant and MacDonald 2003).

3.5 CARDIO-VASCULAR SYSTEM

As in all bivalves, the pectinid circulatory system is said to be open, since venous hemolymph is collected chiefly in a number of well-developed sinuses. However, as Jones (1983) has pointed out, the term "open" should not be taken to mean that capillary vessels are absent. In fact, capillaries are visible in injected preparations (Drew 1906; Dakin 1909), and little is actually known concerning the microcirculation of bivalves.

3.5.1 General Circulation

The general circulation has been described in *Placopecten magellanicus* (= *Pecten tenuicostatus*) by Drew (1906), in *Pecten maximus* by Dakin (1909), and in *Argopecten irradians* by Gutsell (1931); this knowledge base has not since been significantly expanded. The following description is therefore based essentially on these sources. The general circulation may be divided into an arterial and a venous system (Figs. 3.19.1, 3.19.2).

3.5.1.1 The arterial system

Two main vessels constitute the central elements of the arterial system: the anterior and posterior aortas.

3.5.1.1.1 Anterior aorta

The anterior aorta supplies most of the visceral mass and is thus the more complex of the two vessel systems. It arises from the dorsal-most margin of the ventricle and curves dorsally around the digestive gland. Almost immediately after leaving the ventricle, it gives off a left and a right branch which supply blood to the digestive gland; these are visible at the surface of the gland as they begin to ramify and enter the gland itself.

The main branch of the aorta passes over the right side and into the anterior region of the digestive gland, producing ramifications, which pass through the gland to the left side and the left mantle lobe. Just before entering into the digestive gland, a branch separates from the aorta and continues dorsally and anteriorly. This is the anterior pallial artery; it bifurcates to form the left and right circumpallial arteries, which follow the margins of the left and right mantle lobes, branching off small connections to the mantle and becoming progressively smaller in diameter until they meet with the corresponding posterior circumpallial arteries. Drew (1906) states that in *Placopecten magellanicus* (= *Pecten tenuicostatus*) the posterior pallial vessel also arises from the anterior aorta, whereas Dakin (1909) affirms that in *Pecten maximus* it arises from the posterior aorta.

From within the digestive gland, the aorta gives off a branch, which passes anteriorly to supply the dorsal lip and the outer labial palps. As the aorta continues ventrally within the gland, it gives rise to another branch, which proceeds ventro-anteriorly and then curves dorsally into the foot. This is the pedal artery, and at its point of inflection it bifurcates, sending a vessel which supplies the lower lip and inner labial palps.

The aorta continues ventrally, giving rise to another branch running posteriorly to the digestive gland, then dividing into three vessels from within the gonad, supplying both the gonad and the convoluted intestine.

3.5.1.1.2 Posterior aorta

The posterior aorta chiefly supplies the rectum, the adductor muscle and the two mantle lobes. It leaves the ventral-most margin of the ventricle and proceeds ventrally

along the rectum for a short distance before dividing into three branches. One of these continues along the rectum, supplying it with small branches to its extremity. A second curves dorsally to the fused mantle margin, where it bifurcates to become the right and left posterior circumpallial arteries. These vessels follow the mantle margin to meet with the anterior circumpallial arteries. The third branch of the posterior aorta constitutes the adductor artery. It runs antero-ventrally to the adductor muscle, ramifying most extensively from a point near the centre of the striated portion of the muscle.

Figure 3.19. Schematic illustration of the arterial and venous systems in *Pecten maximus*. Figure 3.19.1. Arterial system. AA, adductor muscle artery; AAO, anterior aorta; AM, adductor muscle; APA, anterior pallial artery; AU, auricle; CA, circumpallial artery; F, foot; HA, hepatic artery; L, lips; PA, pedal artery; PAO, posterior aorta; PPA, posterior pallial artery; RA, rectal artery; VA, visceral arteries; VE, ventricle. Figure 3.19.2. Venous system. AV, adductor muscle veins; DS, dorsal sinus; HV, hepatic vein; K, kidney; PV, pedal vein; VS, ventral sinus; VV, visceral veins. After Gutsell (1931).

3.5.1.2 *The venous system*

In addition to blood vessels, the venous system comprises a number of sinuses, which collect blood from the various body parts. These sinuses are all located along the margin of the adductor muscle.

A large hepatic vein runs ventrally to join the pedal vein in a dorsal sinus, located between the pericardium and the adductor muscle. Venous blood from the muscle also flows into this sinus, which communicates with the dorsal extremities of the right and left kidneys. Two ventral sinuses situated on the antero-ventral margin of the adductor muscle extend antero-dorsally to enter the dorsal extremities of the respective right and left kidneys.

Most of the blood from the intestine and visceral mass flows through distinctly visible veins at the surface of the gonad to the external sides of the kidneys, where the veins communicate with the small kidney vessels. In summary, therefore, all returning blood thus far described passes into the kidneys. From there, the blood flows toward the right and left afferent branchial vessels in the right and left gill axes. After circulating in the gills (as described in Section 3.3), the blood joins the right and left efferent branchial vessels within the right and left gill axes. These vessels continue dorsally between the digestive gland and the adductor muscle, opening into the apices of the auricles. The right and left pallial veins join the corresponding efferent branchial vessels just prior to their entry into the right and left auricles; they drain blood from the very fine vessels and lacunae of the right and left mantle lobes.

3.5.2 *The Heart*

Scallops possess a typical bivalve heart composed of two auricles and one ventricle. In addition to its contractile role, the heart is also involved in excretion, as outlined below.

3.5.2.1 *The ventricle*

The ventricle is a smooth-walled chamber with a rather complex morphology (Dakin 1909). The rectum passes through the central portion of the ventricle, which is sac-shaped, while on either side joining the corresponding auricles are two pouches, thus creating a chamber with three very incompletely separated compartments. Both Drew (1906) and Dakin (1909) mentioned the existence of muscular sphincters or valves between the auricles and the ventricle; these structures may be seen in the histological section of Fig. 3.20.1. The valves presumably ensure a one-way flow of blood from the auricles to the ventricle.

The chamber of the ventricle is traversed by numerous muscle fibres, giving a distinct spongy appearance in section. This arrangement, also found in the auricles, is responsible for the great degree of contraction of the heart (Fig. 3.20.1).

3.5.2.2 *The auricles and their excretory structures*

The internal structure of the auricles resembles that of the ventricle, with criss-crossing muscle fibres and numerous lacunae (Figs. 3.20.1–3.20.3). The walls of the auricles are not smooth, as is the case for the ventricles, due to the presence of lateral, papillose outgrowths, which constitute the pericardial gland. This gland was observed by Dakin (1909) to be a site of nitrogenous waste uptake in *Pecten* spp. Although some differences of opinion exist, most recent studies on this system tend to confirm that haemolymph is ultrafiltered via numerous podocytes in this gland from the auricles to the pericardial cavity (see Jones 1983 for review). More recently, Morse and Zardus (1997) have confirmed this function in the pectinids *Chlamys hastata*, *Placopecten magellanicus*, and *Patinopecten caurinus*. In these pectinids, the ultrafiltrate passes to the kidneys via pedicels at the bases of the podocytes (Morse and Zardus 1997).

A second type of excretory cell, the *pore cell*, is found beneath the podocyte-containing outer epithelium of the pericardial gland, within the underlying muscular-connective tissue. These cells are capable of taking up large organic molecules (Morse and Zardus 1997), functioning to prefilter the haemolymph prior to ultrafiltration by the podocytes. They are naturally brown in colour, giving this region a brownish colour in living specimens. The pericardial cavity thus participates in at least two important physiological processes: refilling the heart (as mentioned in Section 3.5.2.4.1), and excretion (in which it acts as a reservoir for the auricular ultrafiltrate). More will be said of the excretory functions of this structure in Section 3.6.1.

A band of myocardial tissue situated on the ventral part of the pericardium connects the two auricles.

3.5.2.3 *Structure and ultrastructure of heart cells*

Scallop and other bivalve myocardial cells present some marked differences from vertebrate cardiac muscle cells. Sarcolemmic and T-tubules are absent in scallop myocardial cells, while the sarcoplasmic reticulum forms a network of tubules extending throughout the cell. This contrasts with adductor muscle cells, in which the sarcoplasmic reticulum is situated only under the sarcolemma. Stimulus for calcium release in scallop myocardial cells is presumably initiated at the sarcolemma and propagated along the sarcoplasmic reticulum to the interior of the cell (Sanger 1979).

Electron microscopic observations reveal the existence of both thin and thick filaments in the myocardial cells (Sanger 1979). The diameter of the thin filaments (6 nm) corresponds to that of actin, while the rather large diameter of the thick filaments (40 nm) led Sanger (1979) to suggest that they were composed of both myosin and paramyosin. Although Dakin (1909) believed that the myocardial muscle fibres of *Pecten maximus* were not striated, it is now known that scallop heart muscle fibres are striated, presenting distinct solid Z-bands (Sanger 1979).

Both intercalated discs and gap junctions are observed in scallop myocardial cells (Sanger 1979), as is true for oyster and mussel heart cells (Irisawa et al. 1973); hence, these cells are both mechanically and electrically coupled, in contrast to scallop adductor

muscle cells which present intercalated discs only and are thus mechanically but not electrically coupled (Sanger 1979). The scallop heart, like that of all other bivalves, therefore constitutes a functional syncytium.

Figure 3.20. Structure of the pectinid heart and haemocytes. Figure 3.20.1. Histological section of a juvenile specimen of *Pecten maximus*, showing the anatomical relationships of the heart to surrounding structures. Note the sponge-like appearance of the heart due to the abundant crisscrossing muscle fibres. am, adductor muscle; au, auricle; dg, digestive gland; i, intestine; k, kidney; p, pericardium; v, valve-like structure between the auricle and ventricle (ve). Figure 3.20.2. Histological section through the auricle (au), efferent branchial artery (eba), and valve (v) of a juvenile specimen of *Pecten maximus*. Other abbreviations as in Fig. 3.20.1. Figure 3.20.3. Detail of Fig. 3.20.2 showing the auricular insertion of the efferent branchial artery and associated valve. Abbreviations as in Fig. 3.20.2. Figure 3.20.4. Transmission electron micrograph of haemocyte types I and II in *Chlamys varia*. Haemocyte type I: lobed nucleus (n) with associated juxtanuclear body (jb), around which are found numerous round mitochondria. The smooth endoplasmic reticulum (ser) is extremely well-developed and dilated, forming abundant saccules. The ectoplasm (ect) presents pseudopodial-type elongations, and vacuoles (v) of apparently endocytotic origin are visible. Haemocyte type II: the irregular nucleus (n) contains a small nucleolus (nu) close to the nuclear envelope. Numerous elongated mitochondria (m) are dispersed throughout the cytoplasm, which is chiefly occupied by dilated smooth endoplasmic reticulum (ser). A large, electron-dense granule (g) is present. Figure 3.20.5. Transmission electron micrograph of a type III haemocyte. Note the irregular nucleus (n), with its characteristic indentation near the cell centre. Numerous mitochondria (m) are grouped near this indentation. Rough endoplasmic reticulum (rer) and free ribosomes (rb) are abundant, while smooth endoplasmic reticulum (ser), showing dilated vesicles, is less common. Microfilaments (mf) are present at the boundary between the organite-rich endoplasm and the ectoplasm (ect). Vacuoles (v) are relatively abundant. Micrographs courtesy of P. Beninger and M. Auffret, Université de Bretagne Occidentale.

The fine innervation of the bivalve myocardium has not been extensively studied. Nerve endings with at least two different vesicle types are closely associated with the myocardium; these two vesicle types may correspond to different neurotransmitters (Sanger 1979).

3.5.2.4 Contraction

The contraction of the scallop heart may be divided into four related phenomena: refilling, coordination of the alternate auricular-ventricular beat, pacemaker mechanism, and regulation of the pacemaker mechanism.

3.5.2.4.1 Refilling

The passage of venous blood through large sinuses would intuitively result in low venous blood pressure, especially in light of the initially low systolic ventricular pressures of bivalve hearts, including those of scallops (see Jones 1983 for review). Ramsay (1952) proposed a mechanism of refilling in the hearts of invertebrates possessing a pericardial cavity. This mechanism was developed by Krijgsman and Divaris (1955) to explain the refilling of the bivalve heart; it has come to be known as the “constant volume” or

“volume-compensating” mechanism. These authors concluded that contraction of the ventricle decreases the hydrostatic pressure in the pericardial cavity, thus forcing the auricle walls to expand; hence ventricular contraction automatically results in auricular expansion. This may be readily verified by cutting or piercing the pericardium at any point - the auricles and ventricle then fail to expand to any appreciable extent. The one-way valves at both extremities of the auricles ensure that auricular contraction will also automatically result in ventricular expansion.

Recent measurements indicate that the pericardium has a consistently lower pressure than either the auricles or the ventricles at all stages of the beat cycle of the bivalve heart; consequently it will promote the expansion of whichever chamber is in diastole (Jones 1983). Although there are some objections to this model, there is little doubt that it forms the basis for the refilling of the bivalve heart (see Jones 1983 for review).

3.5.2.4.2 Coordination of alternate AV beat

The volume-compensating mechanism provides an obligate mechanical link between the auricular and ventricular contractions, thereby ensuring a certain coordination of their respective beats. The actual coordinating stimulus is also purely mechanical, being mediated by alternate stretching of the auricular and ventricular myocardia. There appears to be no direct electrical interaction between the auricles and ventricle (Uesaka et al. 1987).

3.5.2.4.3 Pacemaker mechanism

The case for a diffuse myogenic pacemaker in the bivalve heart was put forward by Krijgsman and Divaris (1955); this has since become conventional wisdom (Brand and Roberts 1973; Jones 1983). Supporting evidence for the myogenic nature of the pacemaker comes from the electrocardiogram of the bivalve heart, which resembles a true myogram, with no trace of nervous impulses (Krijgsman and Divaris 1955). The pacemaker action potential is thus probably initiated by relatively unmodified myocardial cells.

Evidence for the diffuse nature of the myogenic pacemaker is much more equivocal. While denervated heart preparations amply demonstrate the existence of the pacemaker within the heart itself, contradictory results have accumulated which variously indicate a truly diffuse pacemaker, a relatively local pacemaker, and a “wandering” pacemaker in bivalve hearts (Jones 1983). We are unaware of any studies on the location of the pacemaker in pectinids.

Although no accounts of scallop heart action potential have been published to date, other bivalve species exhibit one of three different types of action potential: fast, slow, and spike-plateau. It has been suggested that these differences may be related to phylogeny (Jones 1983).

3.5.2.4.4 Regulation of pacemaker

The bivalve heart receives nerves from the cerebrovisceral connectives; hence, cardiac nerves enter both the right and left auricle (Jones 1983). These nerves originate in the parietovisceral ganglion (Krijgsman and Divaris 1955), and they contain both inhibitory and excitatory fibres (Jones 1983). As mentioned previously, the two different types of vesicles found in the nerve endings may correspond to different neurotransmitters; however, it should be noted that the neurochemistry of the bivalve heart is an evolving field and it is difficult to present a coherent synopsis at this point (see Jones 1983 for review).

On a functional level, it is clear that the pacemaker frequency may be modified by environmental or endogenous physiological factors. Brand and Roberts (1973) observed hypoxia-induced bradycardia followed by an overshoot when preparations of *Pecten maximus* were restored to normoxic conditions. Thompson et al. (1980) demonstrated a regulation of heartbeat during work in *Placopecten magellanicus*. The cardiac rhythm of this species was shown to increase two to three-fold during the rapid contractions of the adductor muscle valve-snap response.

Reported values for resting heartbeats in scallops maintained in well-oxygenated seawater, measured via electrodes passing through holes in the shell, are as follows: 15–20 beats min⁻¹ in *Pecten maximus* at 12°C (Brand and Roberts 1973), 5–10 beats min⁻¹ in *Placopecten magellanicus* at 5°C (Thompson et al. 1980). Earlier values of 25–30 beats min⁻¹ reported for *Placopecten magellanicus* (Drew 1906) should not be retained, as the conditions of observation and measurement were not provided.

Cardiac output has been determined to be 64 mL h⁻¹ in the previously-described preparations of *Placopecten magellanicus* (Thompson et al. 1980). More studies are required to determine such values in other species.

3.5.3 Haemolymph

The haemolymph of bivalves participates in a variety of physiological functions, including gas exchange, osmoregulation, nutrient distribution, elimination of wastes and internal defence. It also serves as a hydrostatic skeleton, such as during movements of the labial apparatus, tentacles, foot, and mantle edges.

Most bivalves lack circulating respiratory pigments (Booth and Mangum 1978; Barnes 1987), and there are no reports of such pigments in any scallop species. Certainly the low oxygen uptake efficiency of the haemolymph of *Placopecten magellanicus* (42% - Thompson et al. 1980) tends to confirm the lack of haemolymph respiratory pigments in this species. The essentially sedentary life habit, the enormous exposed body surface area, and the epibenthic habitat of scallops probably obviate the need for circulating respiratory pigments.

3.5.3.1 Plasma

Studies concerning the chemical composition of marine bivalve plasma have been reviewed by Burton (1983). The steady-state osmotic concentration of the plasma is equal to or marginally greater than that of the surrounding seawater. A slight hyperosmolarity may be necessary to the maintenance of urinal flow and mucus secretion. In any event, the metabolic cost of maintaining a significant long-term plasma-seawater osmotic gradient would be prohibitive in organisms such as bivalves which have vast surface areas exposed to the external medium (Burton 1983).

Most pectinid species are marine, some inhabit reduced-salinity waters, and none are adapted to freshwater (the current common name for *Placopecten magellanicus* - 'sea scallop' - is rather inappropriate, since there are no freshwater scallops). The ionic composition of the haemolymph in *Chlamys opercularis* has been studied by Shumway (1977); concentrations of Na^+ , Mg^{2+} and Ca^{2+} , as well as overall osmotic concentration, followed that of the external medium in short-term fluctuating salinity regimes. The plasma K^+ concentration of bivalves is greater than that of seawater by a factor of 1–2 (Burton 1983); this probably reflects the normal intracellular-extracellular K^+ gradient (Natochin et al. 1979; Hochachka and Somero 1984).

Bivalve plasma contains numerous dissolved organic molecules. Little information is available on this subject for scallops, with the notable exception of *Placopecten magellanicus* (Thompson 1977). Plasma determinations performed immediately after field sampling yielded the following values (means and standard deviations): protein 153 ± 28 , ammonia -N 0.24 ± 0.12 , total carbohydrate 5.2 ± 1.2 , lipid $13.7 \pm 2.4 \text{ mg } 100 \text{ mL}^{-1}$. It should be noted that plasma metabolite concentrations are influenced by physiological events such as short-term osmoregulation (see Pierce 1982) or the reproductive cycle (Thompson 1977). The subject of osmoregulation in bivalves is not within the scope of the present chapter; the reader is referred to Pierce (1982) and Beninger (1985) for a review and references.

3.5.3.2 Haemocytes

Although there are many descriptions of bivalve haemocytes in the literature, the lack of a universal classification scheme has greatly hindered attempts to draw together existing knowledge (Auffret 1988). Indeed, for a single bivalve species, a table of reported haemocyte types and names spans two full pages (Cheng 1996). In an extensive review paper, Cheng (1981) proposed a classification based on three categories of cell populations: hyalinocytes, granulocytes and serous cells. While this scheme may apply to most bivalves, Auffret (1985) did not observe any typical granulocytes in either *Pecten maximus* or *Chlamys varia*, and he did not consider the serous cells to be true haemocytes, since they have a different histological origin. As this appears to represent the only recent study of pectinid haemocytes, the cell types will be summarised here, with special reference to *Chlamys varia*.

3.5.3.2.1 Haemocyte types

Type I haemocytes contain central, lobed nuclei with abundant chromatin, partially condensed into *small* clots and a peripheral chromatin shell. Many *round* mitochondria are situated close to the nucleus; in *C. varia* these form a typical juxtannuclear body. The endoplasmic reticulum (ER) is smooth and often dilated to form numerous saccules. Electron-dense granules are rare (in contrast to the granulocytes of other bivalves), but there are numerous cytoplasmic inclusions and some glycogen particles, as well as vacuoles of apparently endocytotic origin (Fig. 3.20.4).

Type II haemocytes have non-lobed, eccentric nuclei containing abundant chromatin, either uncondensed or condensed in *large* masses of heterochromatin; a peripheral chromatin shell and nucleolus are also present. The numerous mitochondria are *elongated* and distributed throughout the cytoplasm. The smooth ER resembles that of the type I haemocytes except that it is even more vesiculated, filling most of the cytoplasm. Large electron-dense granulations are sometimes present (Fig. 3.20.4).

Type III haemocytes were observed in *C. varia* but not in *P. maximus*; inter-specific differences in haemocyte types may thus exist within the Pectinidae. Type III haemocytes have very irregular shapes, and a *polymorphic* nucleus indented near the cell centre, containing numerous clots of heterochromatin and a peripheral chromatin shell. The endoplasm is very dense, with many elongated mitochondria near the nuclear indentation at the cell centre; *rough* ER is well-developed while smooth ER is not; many free ribosomes are present. The ectoplasm is less dense than the endoplasm, containing large, possibly endocytotic vacuoles and microfilaments at the bases of the cell prolongations (Fig. 3.20.5).

3.5.3.2.2 Functions of haemocytes

Circulating haemocytes participate in five classes of physiological function in bivalves: wound repair, shell repair, nutrient digestion and transport, excretion, and internal defence. Details concerning the roles of haemocytes in these functions may be found in the review by Cheng (1981). Briefly, haemocytes intervene in wound repair by successive infiltration, clumping and plugging of the wound (without a fibrinogen-thrombin-fibrin system), followed by wound repair and phagocytosis of necrotic elements. Their known role in shell repair is that of calcium and organic matrix transfer from the digestive gland to the repair site. Haemocytes are present not only in the vascular system, but are also found wandering through tissues (an "open" circulatory system characteristic). They may thus absorb nutrients from the alimentary tract and pass them directly to other tissues, or to developing oocytes (see section 3.7.4.1.3). Thompson (1977) observed seasonal variations in the glycogen content of haemocytes of *Placopecten magellanicus*, with greater levels in summer than in winter.

Haemocytes may participate directly in excretion by absorbing wastes, passing directly across the epithelium of the nephridial tubules into the kidney lumen and thence to the exterior. Serous cells may also participate in excretion, since they originate as the pigmented cells in the pericardial gland. Although such cells were not observed in the

haemolymph of the two pectinids examined by Auffret (1985), they have been observed in the pericardial gland of *Placopecten magellanicus* (Dakin 1909), as mentioned previously. These cells are capable of phagocytosing foreign particles such as carmine (Dakin 1909).

Most recent attention has been directed toward the roles of haemocytes in internal defence (Cheng 1981; Rodrick and Ulrich 1984). Although it is difficult to summarise the often contradictory observations, the following general points may be mentioned. Bivalve leucocytes are capable of phagocytosing foreign materials and degrading them via the lysosomes. The glycogen granules frequently found in bivalve haemocytes (including pectinids - Auffret 1985) may originate from digested bacteria (Rodrick and Ulrich 1984). In this respect, internal defence and nutrition are somewhat interrelated. Haemocytes also intervene in the extracellular lysis of bacteria through the production of circulating lysozymes (Cheng 1975).

3.6 EXCRETORY SYSTEM

The excretory system of bivalves comprises a number of diverse sites of excretory function (see review by Andrews 1988). The principal excretory organs are the auricular and pericardial glands, and the paired kidneys, also called nephridia or (historically) organs of Bojanus, who mentioned them first in 1819. The anatomical relationships of these structures to each other and to the gonad are illustrated in Fig. 3.21. Ubiquitous cells specialised in metal ion transport may also participate in excretory function.

3.6.1 Pericardial (Auricular) Glands

Gröbben (1888) was apparently the first to suggest an excretory function for the glands located in the auricular and pericardial walls of bivalves. However, it was not until 1942 that White demonstrated their excretory function and showed that their products were collected in the pericardial cavity, from whence they presumably exited via the renopericardial canal and kidney. This has since been confirmed for *Mytilus edulis* (Pirie and George 1979). Ultrastructural data show that these glands, also (historically) known as Keber's organs, appear to be the site of primary urine formation (i.e., ultrafiltration) in bivalves (Andrews and Jennings 1993; Morse and Zardus 1997).

There is some understandable confusion in the designation of auricular and pericardial glands. Glands, which originate in the outer auricle wall and project into the pericardial cavity, have been termed both 'auricular' and 'pericardial' glands. We will follow the terminology of Andrews and Jennings (1993): glands originating on the auricular wall are *auricular glands*, while those originating on the inner pericardial wall and projecting into the pericardial cavity are *pericardial glands*.

Auricular excretory glands appear to be the primitive condition in bivalves; their position in the auricle wall appears to impose a size constraint on the glands themselves, since an excessive development here would compromise auricular contraction. Most Pectinidae have auricular glands, but some species such as *Chlamys ruschenbergerii* have both auricular and pericardial glands (White 1942). The following description covers the

general case (auricular glands); a good description of pericardial glands may be found in Eble (2001).

Figure 3.21. Schematic representation of the anatomical relationships between the pericardium, kidney and gonad in pectinids. Figure 3.21.1. The gonad opening to the kidney (modified after Mackie 1984). Figure 3.21.2. Dorsal view of the heart - pericardial cavity - kidney complex in *Chlamys hastata*. Primary urine formation occurs via ultrafiltration of haemolymph across podocytes (P) of auricular gland (curved arrows) into pericardial cavity (PC). Aao, anterior aorta; Au, auricle; In, intestine; Ko, kidney opening or nephrostome; LK, left kidney; PA, posterior adductor muscle; Pao, posterior aorta; RK, right kidney; RPD, right renopericardial duct. Modified from Morse and Zardus (1997).

The auricular glands of *Pecten maximus* and *Chlamys opercularis* were first described by Dakin (1909). More recent histological and ultrastructural studies of pectinid auricular glands include those of Andrews and Jennings (1993) and Morse and Zardus (1997). The general anatomical relationships of the scallop auricular glands are shown in Fig. 3.21.2. The ultrafiltration barrier is the greatly-folded basal lamina of the podocytes which cover the auricular glands. Within the underlying connective tissue are distinctive cells termed *pore cells* or brown cells (Morse and Zardus 1997), which do not appear to participate in ultrafiltration; more will be said of these below. Almost the entire cell volume is filled with secretory products; their numbers in the auricular wall give this structure a slightly brownish colour. Haszprunar (1996) proposed the name *rhogocyte* (= *Leydig's cell*), based on the diagnostic feature of cell membrane slits rather than pores; the semantic difference is perhaps somewhat tenuous. Although quite dense in the auricular wall, as mentioned above, these cells are ubiquitous in the bivalve body and can be found as solitary wandering cells in the haemolymph, and so may be also considered as a type of haemocyte. Although a partial homology to podocytes has been suggested (Haszprunar 1996), substantial ultrastructural differences exist (Morse and Zardus 1997). Pore cells appear to function in metal ion transport, and may have a role in metal detoxification, complementing that of the kidney (see below), and supporting the suggestion of a homology with nephrocytes (Haszprunar 1996).

Ultrafiltered haemolymph flows from the pericardial cavity to the kidneys via the renopericardial ducts or canals (Drew 1906; Pelseneer 1906; Dakin 1909; Potts 1967; and Fig. 3.21.2), where it is further processed as described below.

3.6.2 Kidney

The kidneys of scallops appear as brownish, flattened sacs attached to the adductor muscle, partially occluded by the gonad. As shown in Figs. 3.21.2 and 3.22.1, each kidney consists of a straight tube, surrounded by glandular tissue (as opposed to the U-shaped tube found in many other bivalves). The tube has classically been divided into a proximal or pericardial section, and a distal section or posterior sinus. The proximal sections of the right and left kidney tubules are connected by a transverse branch on their outer surfaces (Dakin 1909). The distal sections terminate in the renal or kidney openings, which open to the pallial cavity (Fig. 3.21). Given their dual function of evacuating kidney fluid and gametes, these openings are also called the reno-genital apertures.

Although historically considered to reflect separate secretory and excretory functions (Franc 1960), the division of the kidney tubule into proximal and distal sections is quite arbitrary, since it is lined by a single type of epithelial cell (Jennings 1984, cited by Andrews 1988). There exists a close anatomical relationship between the kidney and the parietovisceral ganglion (Fig. 3.22.1), and neurosecretory cells have been shown to penetrate the kidney tissue (Le Roux et al. 1987). The kidneys and the pericardial glands usually display a brownish coloration, due to the presence of granular concretions within their cells (Dakin 1909).

The kidney tubules open into numerous glandular ducts, giving the kidney tissue a spongy appearance (Turchini 1923; Andrews 1988), as in Fig. 3.22.2. The columnar external epithelium of the kidney rests upon a lacunar connective tissue, within which are elastic and muscular fibres (Fig. 3.22.2). The glandular cells (nephrocytes) lining the kidney tubules of *Pecten maximus* have a basal nucleus with dispersed chromatin and few organelles, with the exception of numerous mitochondria (Figs. 3.22.3–3.22.6). These cells contain many variously-sized vacuoles, which may fill most of the cell volume (Figs. 3.22.2, 3.22.3, 3.22.6, 3.22.7). Some vacuoles appear empty, while others contain variably electron-dense granules (Fig. 3.22.7) or myelin figures (Fig. 3.22.4). The cell membrane of the basal pole of the glandular cells presents numerous deep indentations (Fig. 3.22.5), while the apical pole is covered with microvilli (Fig. 3.22.3). These two characteristics indicate that these cells are sites of considerable exchanges with the renal fluid. Supporting cells are interspersed among the glandular cells of the kidney tubules (Fig. 3.22.4).

3.6.3 Functions of the Kidney and Pericardial Glands

Numerous authors have attempted to identify the composition of the urinary fluid of bivalves and elucidate the functions of their excretory system (see reviews by Franc 1960; Lucas and Hignette 1983; Martin 1983; Andrews 1988). Dakin (1909) states that uric acid is not found in bivalve kidneys, and that hippuric acid is eliminated by the pericardial glands of scallops. However, with the exception of Brunel's (1938) studies, which mention the existence of an allantoinase, a urease, an allantoinase and a uricase, little is known concerning the processes of organic nitrogen catabolism (Franc 1960).

The site of primary urine formation is now known to be the auricular or pericardial glands (Andrews and Jennings 1993). Further processing occurs within the kidney nephrocytes and pericardial gland pore cells, where various substances, notably metal ions, are accumulated, and which may combine with each other to form intracellular concretions or granules (Fig. 3.22.7). These concretions may either be excreted as solids, re-dissolved and eliminated as solutes, or grow until the intracellular fluid pressure ruptures the glandular cell, liberating the concretions (Franc 1960). Histochemical and ultrastructural studies in various bivalves suggest an apocrine-type secretion of renal concretions as residual bodies via the lysosomal-vacuolar system (Lowe and Moore 1979; Pirie and George 1979; George et al. 1980; Sullivan et al. 1988). In mussels, the concretions observed in the renal cells and in the pericardial gland pore cells are extruded to the renal tubules and excreted with the urine, which thus contains much particulate matter (Pirie and George 1979).

Mineral concretions were discovered very early in the kidneys of a variety of scallops, including *Argopecten irradians* (Kellogg 1892), *Placopecten magellanicus* (Drew 1906), *Pecten maximus* and *Chlamys opercularis* (Dakin 1909). Several of these authors also gave a qualitative chemical analysis of the concretions, showing the predominance of calcium phosphate, the nearly universal absence of urates, and traces of metals such as magnesium and iron (see review by Lucas and Hignette 1983). The accumulation of these metals was considered to represent either a long-term storage, or a

means of detoxification-excretion of toxic elements (Simkiss 1976; Coombs and George 1977).

Using diverse techniques (differential centrifugation, X-ray diffraction, atomic absorption spectrophotometry, microanalysis), the quantitative composition of metals within the concretions has been determined, notably for *Pecten maximus* (George et al. 1980) and *Argopecten irradians* (Doyle et al. 1978; Carmichael et al. 1979). The concretions are chiefly composed of amorphous metal phosphates, which appear to be more closely related to the brushite-monetite series of phosphorites than to apatite (George et al. 1980). In *P. maximus*, for example, the elements Ca, Zn, Mn, and P comprise 50% of concretion dry weight, while organic material constitutes approximately 21–26% of concretion dry weight (George et al. 1980). The organic substances identified are proteins (6–9%) and oxalate (7% - Overnell 1981). In addition to these static observations, studies of the seasonal variations in composition of the concretions have been performed, as well as studies of the dynamics of their formation (see Bryan 1973 and reviews by Lucas and Hignette 1983; Yevich and Yevich 1985).

Through their accumulation of various trace metals in concretions (especially kidney granules), bivalves may act as biological concentrators (Martoja et al. 1975). The analysis of these metals or of their radioactive isotopes may thus be a means of monitoring environmental pollution (Chipman and Thommeret 1970; Masson and Ancellin 1976). The *in vitro* bioaccumulation of cadmium has been demonstrated in this way in the kidneys of *Argopecten irradians* (Carmichael and Fowler 1981). However, extreme care must be exercised in the interpretation of data from environmental monitoring studies, since the natural variation of granule elemental composition may be very large (George et al. 1980).

3.7 REPRODUCTIVE SYSTEM

A sound knowledge of the structure and function of the scallop reproductive system is obviously necessary for the understanding of their ecology, aquaculture and fisheries. For these reasons, the scallop reproductive system merits detailed consideration.

3.7.1 Sexuality: Gonochory, Hermaphroditism, and their Variants

Bivalves have long been considered gonochoric (sexes separate and invariable) in their overwhelming majority (de Lacaze-Duthiers 1854; Pelseneer 1894; Coe 1943b, 1945). The presence of a few hermaphroditic individuals in normally gonochoric species led Coe (1945) to conclude that primary germ cells are potentially ambisexual, cellular differentiation being based on an inhibition of one or the other potentiality via an unknown mechanism. An incomplete inhibition would thus produce animals with varying degrees of hermaphroditism.

Contrary to most bivalve families, the Pectinidae are predominantly hermaphroditic, with many specific and individual variations, and a general tendency towards protandry (producing first male and later female gametes - Coe 1945). Environmental factors may influence sex determination. In *Argopecten irradians*, low food and temperature levels result in male gametogenesis, whereas oogenesis is suppressed if food is absent (Sastry 1968).

Scallops cited as being predominantly gonochoric are *Chlamys tigerina*, *C. striata*, *C. furtiva* (Reddiah 1962), *Placopecten magellanicus* (Drew 1906; Posgay 1950; Naidu 1970), *Patinopecten yessoensis* (Yamamoto 1943) and *Chlamys islandica* (Sundet and Lee 1984). Even in strictly gonochoric species, a low frequency of hermaphrodites may be found (Naidu 1970; Merrill and Burch 1960; Wakui and Obara 1967; Ozanai 1975), while gonochoric features may be found in some normally hermaphroditic species (Mason 1958).

Most simultaneous hermaphroditic scallop species (male and female gametes developing at the same time) have gonads with distinct male and female portions, the male portion of the gonad being proximal and the female portion distal. However, a general tendency toward protandry precludes self-fertilisation in most cases (Sastry 1963; Fretter and Graham 1964). Although self-fertilised eggs are considered inferior to cross-fertilised ones in *Aequipecten irradians concentricus* (Sastry 1965), self-fertilisation may be a natural phenomenon in *Pecten maximus* (Wilkins 1978).

3.7.2 Origin and Formation of the Gonad

In the postlarval scallop, the gonad differentiates after most of the other organs; the organogenesis of this structure will therefore be described here. Primordial germ cells first appear in juvenile *Chlamys varia* in the region bounded dorsally by the pericardium, anteriorly by the developing kidney, and postero-ventrally by the margin of the adductor muscle. They arise from a group of mesodermal cells (Raven 1966; Wada 1968), and may be observed in *Chlamys varia* in animals as young as 6 months, measuring only 2–3

mm (Lucas 1965). In most pectinids, however, the gonad reaches its first maturity after one year (Reddiah 1962; Ozanai 1975).

Development of the gonad begins with the ventral extension of primordial germ cells in the form of tubules accompanied by loose connective tissue (Coe 1943a, 1945; Lucas 1965). The tubules then become folded, assuming the acinal-type structure of the gonad. The evacuating ducts differentiate as the germ cells multiply along the walls of the acini. This ontogenetic sequence suggests that a tubular gonad organisation is primitive. It is also very rare in the Bivalvia, being reported in the highly-modified, deep-sea endosymbiont-bearing protobranch *Acharax aline* (Beninger and Le Pennec 1997).

3.7.3 Anatomy, Histology, and Ultrastructure of the Adult Gonad

Since the first published anatomical description of a pectinid gonad (*Chlamys varia*) by de Lacaze-Duthiers (1854), numerous authors have used basic histological techniques to study the dynamic anatomy of this organ in various scallop species. Sastry (1979) provides a list of fifteen pectinid species whose spawning periods have been determined, usually by microscopic examination of the gonad. Surprisingly few ultrastructural studies of gonad structure and gametogenesis have been performed in bivalves, notably those of Pipe (1987a, b - *Mytilus edulis*), Eckelbarger and Davis (1996a, b - *Crassostrea virginica*), Beninger and Le Pennec (1997 - *Acharax alinae*), and Eckelbarger and Young (1999 - *Bathymodiolus childressi*). Fortunately, similar studies have also been performed in some detail for various pectinid species (Dorange et al. 1989a, b, c, d). The following account is based on this body of work, supported by micrographs.

In summary description, the gonad contains a large number of acini, whose walls are composed of connective tissue and primary germ cells. The lumen of the acinus is more or less filled with sex cells in varying stages of gametogenesis, depending on the reproductive state of the gonad. The acini empty into a network of ramified evacuating tubules, which consolidate as they approach the kidney (Figs. 3.21, 3.23.3, 3.27.1, 3.27.2). The gametes are shed into the pallial cavity via the renogenital openings of the right and left kidneys. The intestine and part of the crystalline style also occupy some of the gonad (see Section 3.4). Between these structures is a lacunar connective tissue, and the gonad is bounded by a thick outer epithelium (Figs. 3.23.1, 3.23.3).

Although in many species, the male gonad (or portion in simultaneous hermaphrodites) is yellowish-white and the female gonad (or portion) is variably reddish, sexing cannot be accomplished on the basis of gonad colour in all scallop species (Lucas 1965; Mottet 1979).

3.7.3.1 Outer epithelium

Apart from the brief descriptions of Mason (1958, 1963) for *Pecten maximus* and Lucas (1965) for *Chlamys varia*, most of our knowledge concerning the outer epithelium is derived from the electron microscopic studies of Dorange et al. (1989a) for *Pecten maximus*. The following description is based on the observations of the latter study.

Figure 3.23. Structure of the female gonad in *Pecten maximus*. Figure 3.23.1. Histological section of the outer portion of a mature female gonad. bl, basal lamina; ct, perigonadal connective tissue; h, haemocytes; n, nucleus containing dispersed heterochromatin; nu, nucleolus; o, oocyte; oe, outer epithelium; s, haemolymph sinus; v, vitellus. Masson trichrome stain. Figure 3.23.2. Histological section of the interior of a mature female gonad, showing mature (m) and pedunculated (p) oocytes. Masson trichrome stain. Figure 3.23.3. Histological section of a partially-spawned female gonad. Most remaining oocytes are pedunculated. Abbreviations: a, acinus; e, evacuating duct opening into acinus; oe, outer epithelium. Masson trichrome stain. Figure 3.23.4. Transmission electron micrograph of the gonad outer epithelium. bl, basal lamina; cc, ciliated cells; mc, non-ciliated microvillous cells; mf, muscle fibres. Figure 3.23.5. Low-power scanning electron micrograph of the gonad outer epithelium. cc, ciliated cell; mc, non-ciliated microvillous cell. Figure 3.23.6. Scanning electron micrograph detail of the gonad outer epithelium. m, microvilli; c, cilia. Micrographs courtesy of G. Dorange, Université de Bretagne Occidentale, France.

The outer epithelium is generally cuboidal, although some regions containing non-differentiated cells may show a pseudostratified appearance. Three cell types dominate in the epithelium: microvillous cells, ciliated cells, and mucocytes. Ultrastructural details for each cell type may be found in Dorange et al. (1989a). These cells rest upon a thick, often deeply-folded basal lamina, indicative of translocation (Figs. 3.23.1, 3.23.4).

3.7.3.2 Perigonadal connective tissue

The perigonadal connective tissue contains various cell types, as well as abundant collagen fibres. Smooth muscle cells are frequently observed (Figs. 3.23.1, 3.27.1); hence the designation “muscular-connective tissue” is in fact more appropriate. Mason (1958, 1963), suggests that this muscular-connective tissue may, through localised contractions, assist in the evacuation of gametes. The myocytes may also aid in the circulation of haemolymph within the gonad (Mason 1958, 1963).

Among the other cell types observed in the perigonadal connective tissue are macrophage-like cells, fibroblasts, and large vacuolar cells. The macrophage-like cells appear to correspond to “quiescent” type II haemocytes, which are not involved in internal defense, but rather in the assimilation and transport of the products of gamete lysis following atresia (Poder 1980; Dorange et al. 1989b). This topic will be dealt with in detail in Section 3.7.4.

3.7.3.3 Inter-acinal connective tissue

Since the gametes are produced in acini and not follicles, the name inter-acinal connective tissue is now widely used to describe the lacunar tissue found between the acini. It is structurally similar to the perigonadal connective tissue (Fig. 3.23.1). The amount of this tissue varies throughout the reproductive cycle, and it probably serves as an energy reserve for the developing gametes (Coe 1943a; Beninger 1987; Eckelbarger 1996a).

3.7.3.4 Haemolymph sinuses

These sinuses are present beneath the perigonadal connective tissue (Figs. 3.23.1, 3.27.1), and are particularly abundant in the inter-acinal connective tissue and at the periphery of the evacuating ducts; the intestinal loop is surrounded by a large sinus (Fig. 3.25). They are frequently associated with the infoldings of the outer epithelia, hence increasing the amount of surface area for exchange. Numerous haemocytes may be observed in these sinuses (Section 3.5), and macrophagous type II haemocytes are also present in the acini among the debris of oocyte lysis after spawning, during sexual resting periods, and in the later stages of atresia (Section 3.7.4).

3.7.3.5 *Acini*

The acini are bulb-shaped structures composed of an outer layer of connective tissue, from which presumably arise the inner layer of primordial germ cells; the gametes produced by these cells are eventually drained by the evacuating ducts. The developing gametes are readily visible along the inner margins of the acini, variably filling the lumina depending on the stage of gametogenesis (Figs. 3.23.2, 3.23.3, 3.27.1, 3.27.2, and Section 3.7.4).

3.7.3.6 *Evacuating ducts*

The ciliated columnar epithelium of the evacuating ducts rests upon a basal lamina, which is irregular at the junction of the gonoduct and acinus.

3.7.4 Gametogenesis

Gametogenesis and spawning are controlled by both endogenous and exogenous factors, among which the most important are temperature and food (Sastry 1966, 1968; Taylor and Capuzzo 1983). The process of gametogenesis in bivalves has been detailed in several works, such as those by Raven (1961), Sastry (1979), Dohmen (1983), Pipe (1987), Eckelbarger and Davis (1996a, b), and Morse and Zardus (1997). For the pectinid family, the principal histological studies are those of Coe (1945), Mason (1958, 1963), Lubet (1959), Reddiah (1962), Sastry (1963, 1966), Lucas (1965), Naidu (1970), Allarakh (1979). Ultrastructural studies have been performed on the gonads of *Pecten maximus* (Dorange et al. 1989a, b, c, d), allowing a better understanding of the events involved in the reproductive cycle. The following description is based largely on these ultrastructural studies.

3.7.4.1 *Oogenesis*

In pectinids, as in all other molluscs (and most other animals as well), complete meiosis of the female gametes is delayed until after spawning and fertilisation (see Longo 1983 for review). The mature scallop oocyte is blocked in the first metaphase of meiosis; the remaining meiotic stages are rapidly accomplished after fertilisation. This is readily observed *in vitro* by the appearance of polar bodies after fertilisation (Desilets et al. 1995).

Oogenesis may be divided into three distinct stages: premeiotic, previtellogenic, and vitellogenic.

3.7.4.1.1 *Premeiotic stage*

The stem cells, which constitute the boundaries of the acini, give rise to primary oogonia (8–10 μm), characterised by a high nuclear-cytoplasmic ratio. The nucleus contains clumped chromatin and occasionally a single, 3–4 μm nucleolus. Some mitochondria and endoplasmic reticulum cisternae are present in the cytoplasm. The

germ cells divide mitotically to produce secondary oogonia. This stage is termed premeiotic because all divisions are purely mitotic.

3.7.4.1.2 Previtellogenic stage

The secondary oogonia enter into the first prophase of meiosis to give previtellogenic oocytes (Raven 1961). During the previtellogenic stage, the nucleus and cytoplasm of the oocyte increase in volume. The ultrastructural characteristics of the nucleus reveal young oocytes in leptotene, zygotene-pachytene and diplotene stages of prophase (Fig. 3.24.2). In leptotene, the chromosomes become visible whereas the nucleolus disappears. In zygotene-pachytene, the round or ovoid cells are easily identified due to the presence of the synaptonemal complex and the familiar lamp brush chromosomes.

As they enter diplotene, the oocytes elongate (Fig. 3.24.2). With the reappearance of the nucleus, dense aggregates (probably nuclear extrusions rich in ribonucleotides) accumulate in the cytoplasm. At this stage, auxiliary cells (Coe 1943a; Mason 1958, 1963; Raven 1966; Dorange et al. 1989c) migrate from the periphery of the acinus, establishing an intimate contact with the developing oocytes (Figs. 3.24.2, 3.24.4). The ultrastructural characteristics of the auxiliary cells in *Pecten maximus* are similar to those described for *Mytilus edulis* (Pipe 1987) and *Crassostrea gigas* (Eckelbarger and Davis 1996a). These cells participate in oocyte maturation as described below.

3.7.4.1.3 Vitellogenesis and metabolite transport to the oocyte

Knowledge of the exact pathways and mechanisms of metabolite transfer to the developing gametes is rather limited. A summary of known and proposed pathways may be found in Le Pennec et al. (1991), including a proposed pathway from the gonad-intestinal loop. Experimental support for this pathway has been provided using ferritin histochemistry (Beninger et al. 2003). Ferritin molecules are absorbed by the intestinal epithelial cells, transferred to the basal lamina, incorporated into vacuolated haemocytes, which migrate along connective-tissue fibres to the acini (Fig. 3.25). The haemocytes are able to penetrate the acinal basal lamina, and transfer the ferritin to developing oocytes. It is quite possible that similar haemocytes arrive in the acinus from the digestive gland. The relationship between these migrating haemocytes and auxiliary cells (see below) is not yet clear; the latter may serve as intermediaries.

Developing oocytes enter into vitellogenesis in the diplotene stage (Dorange et al. 1989b). Their size increases and they progressively become pedunculated (Figs. 3.24.1, 3.24.4). Various nuclear, cytoplasmic and membranal modifications occur before the oocyte detaches from the acinus wall.

Cortical glycoprotein granules become progressively denser in the cytoplasm while the oocyte is still largely attached to the underlying connective tissue. At this stage the ER is abundant. As the oocyte develops, the cortical granules and Golgi apparatus multiply. There is an intense production of vesicular and lamellar ER, as well as of various vitelline inclusions (Fig. 3.24.3). Three or four dictyosomes also appear at this point.

Figure 3.25. Anatomy of the proposed intestinal loop pathway of metabolite transfer to developing oocytes in *Pecten maximus*. Semi-thin sections of the epithelium of the gonad intestinal loop. Toluidine blue stain. Figure 3.25.1. Low-power micrograph showing proposed anatomical pathway for transfer of metabolites from intestine to haemocyte (H)-vesicular cell (VC) couples, and thence to acini (A) via intestine-acinus transfer complex (IAC), and connective fibres (CF), within loose connective tissue (LCT). Figure 3.25.2. Detail of an intestinal-acinus transfer complex, showing greatly-vacuolated vesicular cells (VC) along pathway to acinus. Smaller haemocytes (H), with extensive filamentous cytoplasmic projections, can be seen in close contact with the vacuolated vesicular cells (arrows). Parts of another pathway may be observed in the upper right quadrant of the micrograph. From Le Pennec et al. (1991).

Throughout oogenesis, the attached auxiliary cells also present cytological modifications as their cytoplasmic volume increases. The granular ER multiplies, indicating intense protein synthesis. Mitochondria, smooth ER vesicles, α -glycogen vesicles and lipid-like globules appear in the cytoplasm. Similar ultrastructural changes have been observed in the auxiliary cells of *Mytilus edulis* (Pipe 1987) and *Crassostrea gigas* (Eckelbarger and Davis 1996a). Endocytotic figures may be seen between the developing oocyte and the auxiliary cell, indicating a transfer of nutrients.

The plasma membrane changes as the oocyte becomes peduncular. At the apical pole, microvilli appear and a fibrillar glycocalyx develops, forming the vitelline envelope. This envelope initially appears close to the auxiliary cell, and progressively surrounds the oocyte (Fig. 3.24.3). Close contact is maintained with the auxiliary cell via zonula adherens type junctions. Near the adherence zone, fibril-containing vacuoles are visible in the cytoplasm of the auxiliary cells.

The auxiliary cells detach from the oocytes at the end of the peduncular stage. The cytoplasm of the auxiliary cells then becomes vacuolated and myelin figures appear, indicative of membrane breakdown.

At the end of vitellogenesis, the thick vitelline envelope is slightly separated from the cytoplasmic membrane by a vitelline space, while vitelline reserves are abundant in the cytoplasm. β -glycogen particles are present, along with typical ringed lamellae whose function is not known. Cortical granules are numerous at the periphery of the oocyte.

The mature oocytes of scallops measure 15–120 μm in diameter, depending on the species (Table 3.1). In a mature gonad, they often assume a polyhedral shape due to crowding in the acini, but resume a rounded shape when spawned.

3.7.5 Oocyte Atresia

One of the first observations of oocyte atresia (necrosis) was that of Tang (1941) in *Pecten maximus*. This phenomenon was later observed in *Chlamys tehuatlana* (Christiansen and Olivier 1971) and *Patinopecten yessoensis* (Ozanai 1975). Although relatively common in bivalves, few ultrastructural studies of oocyte lysis have been performed (see Albertini 1985; Lubet et al. 1986; and Pipe 1987 for *Mytilus edulis*; and Dorange et al. 1989b, c for *Pecten maximus*). Oocyte atresia is usually observed at the end of vitellogenesis, but even previtellogenic oocytes may be affected due to the presence of lytic enzymes, which spread throughout the acinus when other oocytes lyse.

The histological appearance of atresic oocytes is characterised by a modification of their staining affinities, beginning with the nucleus, which loses its basophilic properties. The peripheral cytoplasm then becomes clear, and the oocytes take on a much-deformed "jigsaw-puzzle" appearance (Fig. 3.26.2). Finally, the cell membranes rupture, discharging the nuclear and cytoplasmic contents. In this terminal stage, the oocytes appear as empty, deformed sacs piled against each other (Fig. 3.26.3).

In *Pecten maximus*, the first noticeable ultrastructural modification is the appearance of one or two nodules within the ER, consisting of concentric masses of cisternae. The rough and smooth ER then dilates, accompanied by a vacuolar degeneration of the cell. The mitochondria lose their cristae and become clear and deformed. The nuclear envelope expands into the cytoplasm, and the nucleus becomes multilobed prior to bursting (Fig. 3.26.5). A peripheral cytoplasmic necrosis then develops. Granules (probably from the rupture of the cortical granules) appear between the vitelline envelope and the plasma membrane. The perivitelline space increases, the microvilli detach and the plasma membrane ruptures. Glycogen granules accumulate in the lysed zones and in the vitelline envelope, which finally bursts, discharging the oocyte contents into the acinus (Fig. 3.26.4). Lytic debris spreads among the intact oocytes, while macrophage cells converge in the acinus (Dorange et al. 1989c).

Although the regulating mechanism of oocyte atresia is not well known, Lubet et al. (1986) demonstrated a neuroendocrine control *in vitro* for *Mytilus edulis*; it is probable that a similar mechanism exists in scallops. Environmental stimuli such as temperature may act as cues. In *Pecten maximus* from St.-Brieuc Bay (France), spawning only takes place if the water temperature reaches 15.5–16.0°C; if not, pronounced atresia occurs in the mature gonads (Paulet et al. 1988). Since adductor muscle reserves are at their lowest at this time, it is possible that the lysed oocytes are recycled as maintenance substrates for the animal. Macrophagous type II haemocytes play an important role in the resorption of lytic debris and the redistribution of nutrients to the germ cells, both within the acinus and at the junction of the evacuating duct. Epithelial cells of the evacuating ducts also resorb lytic debris in *Mytilus edulis* (Pipe 1987).

3.7.6 Spermatogenesis, Spermatozoon Ultrastructure, and Taxonomy

Spermatogenesis in scallops has been studied by several authors, notably Lubet (1951, 1959), Mason (1958), Sastry (1963, 1966, 1979), Lucas (1965), and Naidu (1970), using light microscopy; and by Dorange et al. (1989d), using both light and electron microscopy. The following description is based on these studies. Dimensions are for histologically or electron microscopically-processed material.

The developing gametes are grouped in acini (Fig. 3.27.1, 3.27.2). Two cell types are visible in the acinus wall: stem cells, easily recognised by their finely granular nucleus and oval nucleolus, and spermatogonia, which are derived from these cells after several mitotic divisions (Fig. 3.27.3).

The primary spermatogonia are approximately 12 μm long and 7 μm wide. Their oval nucleus is about 5 μm in diameter, containing dispersed clumps of chromatin and one or two nucleoli. Numerous mitochondria are present in the cytoplasm. Primary spermatogonia divide mitotically to produce secondary spermatogonia, from which they are not easily distinguished under the light microscope.

The secondary spermatogonia are numerous at the start of sexual maturity. They measure approximately 7 μm long and 5 μm wide, with a rounded nucleus containing one nucleolus. The chromatin clumps are denser and the cytoplasm is reduced in comparison to primary spermatozoa. During sexual maturation, polynuclear spermatogonia are frequently observed in *Pecten maximus* (Dorange et al. 1989b). The secondary spermatogonia become spermatocytes, which detach from the acinus wall (Figs. 3.27.3–3.27.5). They are slightly smaller than the secondary spermatogonia. Primary

spermatocytes present the various stages of the first meiotic division (Fig. 3.27.3). The first meiotic division products are the secondary spermatocytes, which are rarely observed because the second meiotic division occurs almost immediately. Their nucleus contains a dense network of chromatin (Lucas 1965).

The meiotic division of the secondary spermatocytes produces young spermatids, which differentiate to form older spermatids (Fig. 3.27.4) which are small (approximately 3 μm in diameter), containing a dense, round nucleus (approximately 1.8–2.4 μm). Their most characteristic feature is the 3–5 mitochondrial spheres, which form a collar at the base of the nucleus (Fig. 3.27.4). Several structural changes transform the spermatid into a mature spermatozoon. An annular Golgi structure, consisting of two concentric sacs, forms the acrosome, which elongates, invaginates, and becomes comma-shaped. The sacs then appear to fuse, giving rise to the definitive acrosome. The centriolar system migrates to the base of the nucleus and the distal-most centriole modifies to give rise to the flagellum. Throughout these latter stages of spermatogenesis there is a progressive reduction of the cytoplasm.

The ultrastructure of bivalve spermatozoa has been intensively studied, due to their usefulness in elucidating phylogenetic and taxonomic relationships (e.g., Popham 1979; Hodgson and Bernard 1986; Healy 1995, 1996; Eckelbarger and Davis 1996b; Garrido and Gallardo 1996; Le Pennec and Beninger 1996; Beninger and Le Pennec 1997; Morse and Zardus 1997; Kafanov and Drozdov 1998; Healy et al. 2000). As recently underscored by Healy et al. (2000), specific data for pectinids are scarce; however, the ultrastructural features of *Pecten maximus* have been detailed in Dorange and Le Pennec (1989d) and in the previous edition of this volume (Beninger and Le Pennec 1991). To date, the only comparative study of pectinid spermatozoon morphology and ultrastructure deals with ten species of confirmed pectinids (Le Pennec et al. 2002). The following description is based upon these works.

Two general categories of pectinid spermatozoon have been defined: the more primitive Category 1, characterised by a rounded shape, and the more advanced, elongated Category 2 spermatozoon (Le Pennec et al. 2002). Within these two categories are several groups, based on ultrastructural characteristics, which correspond well with the taxonomic affinities of Waller (1991): the *Pecten* group, the *Palliolium* group, the genus *Hinnites*, the *Aequiptecten* group, the *Chlamys* group, and the *Mimachlamys* group (Fig. 3.28). The ultrastructural distinctions are based on the shape of the nucleus and the acrosomal depressions.

Notwithstanding the differences noted above, the mature scallop spermatozoon contains a dense, granular nucleus with two acrosomal depressions (Figs. 3.27.4–3.27.8, 3.28). The mid-piece presents four to five mitochondrial spheres (diameter 0.7–0.8 μm) (Fig. 3.27.7, 3.27.8), which surround the centriolar system and possess long crests. Together these sections measure approximately 3–6 μm , whereas the flagellum, of 9 + 2 structure, is approximately 45 μm long (Table 3.1 and Fig. 3.28), and 0.2–0.3 μm in diameter; these dimensions are typical of littoral bivalve species (Beninger and Le Pennec 1997). The spermatozoa develop in a centripetal manner, with their flagella toward the lumen of the acinus (Fig. 3.27.2).

Figure 3.28. Schematic representations of pectinid spermatozoa, assembled into Categories 1 and 2, and into Groups (Waller 1991) corresponding to taxonomic affiliations (Le Pennec et al. 2002). For scale, *Pecten maximus* = 1.6 μm width.

3.7.7 Fertilisation

The events of fertilisation have been studied in detail in *Placopecten magellanicus*. Although similar to the accounts of other bivalve species, some differences were observed, notably the absence of a zygote nucleus (the male and female chromosomes align immediately on the mitotic spindle of the first meiotic division). There does not seem to be a general rule for the stage of blockage of the first meiotic division in mature pectinid oocytes, as some species are blocked in prophase and others in metaphase (Desilets et al. 1995).

3.8 NERVOUS AND SENSORY SYSTEMS

The anatomical modifications of scallops (reduction of the anterior region, circumpallial mantle eyes and tentacles, central position of posterior organs such as the adductor muscle) are reflected in the general organisation of the nervous system (Fig. 3.29). Accordingly, the cerebral ganglia are reduced and closely related to the pedal ganglia, while the visceral ganglia are fused and complex, forming the distinctive pectinid parietovisceral ganglion. This structure innervates the majority of the scallop body (Fig. 3.29).

3.8.1 General Organisation of the Nervous System and Functional Anatomy of Principal Ganglia

The scallop nervous system consists of two main ganglionic concentrations and their nerves: the cerebral and pedal ganglia and the parietovisceral ganglion (Figs. 3.29, 3.30).

3.8.1.1 Cerebral and pedal ganglia

The paired cerebral and pedal ganglia are located quite close together beneath the integument, between the ventral lip and the foot. Wilkens (1981) shows them as contiguous structures in *Pecten ziczac*, and this agrees with our own histological observations in *Placopecten magellanicus* (Figs. 3.29, 3.32.1). However, Drew (1906) and Dakin (1909, 1928a) show these two paired structures as being somewhat more distinct in *Pecten maximus*, *Chlamys varia* and *Placopecten magellanicus*. They are linked to each other by a pair of cerebro-pedal connectives. The individual cerebral ganglia themselves are joined dorsally by a circumoesophageal cerebral commissure immediately posterior to the mouth (Fig. 3.30).

Also arising from the antero-dorsal portion of the cerebral ganglia are the right and left anterior pallial nerves, which run toward the oesophagus and through the digestive gland to enter the mantle above the dorsal lip. Here they split into several branches which join the circumpallial nerve (Figs. 3.29, 3.30).

Three smaller nerves also originate from the antero-dorsal region of the left and right cerebral ganglia (Fig. 3.30): the labial nerve, the palp nerve, and the statocystic nerve (the otocystic nerve of Drew 1906 and Dakin 1909).

The pedal ganglia are almost fused due to the massive pedal commissure. A large pedal nerve arises from each ganglion, ramifying and innervating the foot muscles (Figs. 3.30, 3.32.1).

3.8.1.2 The parietovisceral ganglion and its nerves

The paired visceral ganglia characteristic of other bivalve families have become greatly modified in the Pectinidae, being completely fused to form one large, complex parietovisceral ganglion composed of several distinct lobes (Fig. 3.31.1). This is the largest and most intricate ganglion found in the Bivalvia (Bullock and Horridge 1965) and

Figure 3.29. Diagram of the principal ganglia and their nerves in relation to body structure in *Pecten ziczac*. The upper left and lower insets illustrate the innervation of the mantle in the dorsal and ventral regions. Abbreviations: apn, anterior pallial nerve; CG, cerebral ganglion; cpn, circum-pallial nerve; cvc, cerebrovisceral connective; FM, fast striated muscle groups; fm, fast motor nerve; lpn, lateral pallial nerve; PG, pedal ganglion; ppn, posterior pallial nerve; PVG, parietovisceral ganglion; rpm, radial pallial musculature; SM, smooth muscle groups; smn, slow motor nerve. From Wilkens (1981).

as such it merits special attention. The external anatomy of this structure has been described in *Pecten maximus* and *Chlamys* (= *Aequipecten*) *opercularis* by Dakin (1910b, 1928a), in *Argopecten irradians* by Spagnolia and Wilkens (1983), and in *Patinopecten yessoensis* by Matsutani and Nomura (1984). It consists of a large ventrocentral (= posterior) lobe, flanked by two crescent-shaped lateral lobes. Its external anterior surface is surmounted by two bulbous dorsocentral (= anterior) lobes (Fig. 3.32.2). Near the point of insertion of the cerebro-visceral connectives are two spherical structures called accessory lobes (= accessory ganglia), which are considered to be part of the parietovisceral ganglion by Spagnolia and Wilkens (1983), but not by Matsutani and Nomura (1986).

Abbreviations: CT, connective tissue; G, ganglion cells; NP, neuropile region. Micrographs courtesy of A. Donval and P. Beninger, Université de Bretagne Occidentale.

The parietovisceral ganglion is situated slightly postero-ventrally to the excretory pore of the right kidney, and is in close anatomical relation with this organ. It gives rise to most of the nerves of the viscera, adductor muscle, and mantle (along with its specialised sensory structures). Two cerebro-visceral connectives link the ventral parts of the cerebral ganglia to the parietovisceral ganglion (Figs. 3.29, 3.30). Close to the junction with the cerebro-visceral connectives are the large branchial nerves, which innervate the gills. Joining the ganglion on the right and left sides are the pallial nerves, adductor muscle nerves, osphradial nerves, and osphradio-branchial nerves. Ventrally on either side of the ganglion, large posterior pallial nerve tracts arise which curve around the adductor muscle, joining the circumpallial nerve by several branches, and ramifying to innervate most of the mantle. The circumpallial nerve innervates the mantle margin and its associated sensory structures (e.g., tentacles and eyes via the tentacle and optic nerves, respectively), as well as some of the pallial muscles (Figs. 3.29, 3.30, 3.33.1, 3.33.6).

An interesting aspect of the external anatomy of the parietovisceral ganglion are the relative sizes of the two lateral lobes. The left lateral lobe is larger than the right one in *Pecten maximus*; this has been related to the greater number of eyes on the left mantle margin in this species (Dakin 1910b). In *Argopecten irradians*, however, the two lateral lobes are symmetric, corresponding to an equal number of eyes on each side (Spagnolia and Wilkens 1983). The role of the lateral lobes in vision is dealt with in Chapter 5.

3.8.1.3 Histology and neurosecretions of the ganglia

The cerebral and pedal ganglia show similar histological organisation, with a cortex of ganglionic cells from which nerve fibres extend to the core or neuropile region (Fig. 3.32.1). The parietovisceral ganglion presents a more complex internal anatomy. While the ventro-central lobe is composed of a fibrillar neuropile and a peripheral ganglionic cortex, the two dorso-central lobes are almost entirely made up of the largest ganglion cells (Figs. 3.32.2, 3.32.3), whose nerve fibres ramify throughout other regions of the ganglion (Stephens 1978). Most of the pear-shaped ganglion cells are unipolar, but bipolar and multipolar cells also occur. Neuroglia cells and their fibres envelop the ganglion cells, and are also present in the neuropile and in the nerves. There are very few blind endings of nerve fibres in the neuropile (Dakin 1910b).

Much of our knowledge of the nerve tracts of the parietovisceral ganglion is based on the fragmentary observations of Dakin (1910b), presented by Bullock and Horridge (1965) and shown in Fig. 3.31.2. More recently, the routes of the radial pallial nerves were traced within the parietovisceral ganglion of *Argopecten* (= *Aequipecten*) *irradians* by Stephens (1978). The internal structure and nerve tracts of the lateral lobes have been studied in detail by Spagnolia and Wilkens (1983), and are presented in Chapter 5.

Details of the synaptic structure in bivalve ganglia are rather scant, with the notable exceptions of the study by Cobb and Mullins (1973) on the visceral ganglion of *Spisula solidissima*. In this species, most axons were shown to be varicose, containing several types of vesicles, while specialised synaptic contacts were rare or absent. These authors proposed that the varicose axon type may function in a similar manner as the

unspecialised varicose terminals of the vertebrate autonomic neurons. Such studies should be extended to the more complex parietovisceral ganglion of the Pectinidae.

The localisation of serotonin-like monoamines in the scallop ganglia has been performed in several studies (e.g., Chang et al. 1984; Matsutani and Nomura 1986; Paulet et al. 1993). The relation between serotonin and spawning is well-known in many bivalve species, and it is not surprising that serotonin receptors are also situated in the walls of the gonad acini (Matsutani and Nomura 1986). This relation is explored further in Sections 3.8.2.4 and 3.8.3. Other secretions could include growth factor and gonial mitosis stimulating factor, as has been observed in *Mytilus edulis* (Mathieu et al. 1988; Toullec et al. 1988).

3.8.1.4 *The circumpallial nerve*

The circumpallial nerve is located just interior to the circumpallial artery. It is innervated by both the anterior and posterior pallial nerves, which originate in the cerebral and parietovisceral ganglia, respectively. The circumpallial nerves of the two mantle lobes are fused anteriorly and posteriorly at the hinge line. Both Drew (1906) and Dakin (1909) state that this nerve is physiologically a ganglion, since it is well supplied with ganglion cells and contains abundant nerve cells; however, integrative properties do not appear to exist in relation to visual stimuli (see Chapter 5).

3.8.2 Sensory Structures

Knowledge concerning the various sensory structures of scallops is quite unequal. While the visual system has been the object of continued study for over a century, the remaining structures have received much less attention and are still largely enigmatic.

3.8.2.1 *Visual system*

A conspicuous feature of scallops, the eyes have been the subject of some study from time to time in the literature (e.g., Dakin 1910a, 1928b; Land 1965, 1968; Morton 2000). The eyes are distributed around the margin of the middle (sensory) fold of the mantle, and originate at the base of the tentacles (Butcher 1930; Figs. 3.33.5, 3.33.6). The eye itself consists of a cornea, lens, double retina and tapetum (Fig. 3.33.6). Light is reflected off the tapetum to the inverted retina. The optic nerve from each eye joins the circumpallial nerve (Fig. 3.33.6), which is innervated by tracts from the lateral (optic) lobes of the parietovisceral ganglion. A detailed description of visual physiology is presented in Chapter 5.

3.8.2.2 *Epithelial sensory cells and tentacles*

Epithelial sensory cells are probably scattered over the scallop epidermis, but correlative ultrastructural and electrophysiological studies are lacking. Sensory cells are concentrated on papillae in the distal third of the long tentacles, situated at the margin of

the middle mantle lobe (see Section 3.2). The haemocoel of the tentacle contains a central tentacular nerve, surrounded by a protective musculo-connective sheath, and flanked by two longitudinal retractor muscles (Figs. 3.33.1, 3.33.2). Extension of the tentacle is effected by hydrostatic pressure from the haemolymph, which fills the haemocoel; contraction of the longitudinal tentacle muscles causes the tentacles to retract to approximately one-tenth of the extended length (Fig. 3.33.1, 3.33.2). The central tentacular nerve is an extension of the tentacular nerve which radiates from the circumpallial nerve (Figs. 3.33.1, 3.33.2, 3.33.6).

Although histologically similar to ordinary epithelial cells, the tentacle sensory cells are often much narrower and bear cilia much longer than those of the other epithelial cells. The base of the sensory cell is joined to nerve fibres running to the central tentacular nerve (Dakin 1909). The structure and ultrastructure of the ciliated receptor cells on the papillae of the long tentacles of *Placopecten magellanicus* have been studied in detail by Moir (1977a). Each papilla bears three specialised cell types: a supporting cell associated with the putative sensory cell which carries up to five cilia, and a third cell type at the base of the papilla possessing many cilia as well as macrocilia (Fig. 3.34). The sensory cells are known to respond to mechanical stimulation.

3.8.2.3 Abdominal sense organ

The abdominal sense organ was first described in pectinids by Dakin (1909). It is visible as a small, yellowish fold of tissue situated on the adductor muscle near the anus (Fig. 3.33.3). Since Dakin's work this enigmatic organ was virtually ignored, until the detailed structural and ultrastructural study by Moir (1977b) and the electrophysiological studies of Zhadan and Semen'kov (1984) and Zhadan and Doroshenko (1985). Ciocco (1985) also described the histology of this structure. The following is a summary of these authors' work, as well as our own histological data presented here.

The sensory epithelium consists of two basic cell types: sensory cells and mucocytes. Zhadan and Semen'kov (1984) described two categories of sensory cells - those with single, long cilia, and those with multiple, short cilia. These two distinct cell categories are innervated by different nerve fibres, which descend toward the fibrillar inner core (Fig. 3.33.4). A third group of nerve fibres innervates the base of the organ. All three groups of nerve fibres respond to mechanical stimulation of the sensory cells, and are connected to the parietovisceral ganglion via one of the posterior pallial nerves. Each group of fibres exhibits different response characteristics.

Although the structural evidence would indicate a chemosensory role for the abdominal sense organ (Dakin 1909; Moir 1977b), it has also been suggested that it functions in mechanoreception (Charles 1966; Moir 1977b). Zhadan and Semen'kov (1984) and Zhadan and Doroshenko (1985) demonstrated the electrophysiological responses of this organ to mechanical stimulation, and suggested that cAMP and cAMP-dependent phosphorylation may be involved in mechanoreception. However, the hypothesis that it may function in the detection of vibrations such as the approach of a predator (Zhadan and Semen'kov 1984) is tenuous, given the position of the abdominal sense organ on one side of the body, well inside the pallial cavity which is almost totally

From Moir (1977a).

enclosed by the velum. It is more likely that such detection is effected by the extensile sensory tentacles, which are distributed around the mantle. To date, the suggestions of Charles (1966) and Moir (1977b) appear the most plausible: the abdominal sense organ, being situated directly in the path of exhalant water flow within the pallial cavity, probably functions in the regulation of water flow and, thus, in the regulation of feeding.

3.8.2.4 Osphradia

Sensory structures called osphradia are well known in gastropods (see Garton et al. 1984 for references), and zoologists have long supposed that similar structures exist in bivalves. Most authors agree that the osphradia of bivalves are small and difficult to detect (Drew 1906; Bullock and Horridge 1965; Charles 1966). Indeed, Gutsell (1931) was unable to observe osphradia in *Argopecten irradians*. To date, anatomical evidence indicates that in all probability the osphradia of gastropods and bivalves are not homologous (Kraemer 1979).

The early work of Dakin (1909) gives a description of putative osphradial ganglia in *Pecten maximus*, but does not pinpoint their location. Setna (1930) states that in several scallop species, the osphradia are paired sensory structures situated along the most lateral margins of the gill axis as raised ridges of tissue which are only visible in fresh specimens or in histological section. The osphradia are innervated by branches of the branchial nerve, and contain both ciliated sensory cells and bipolar neurons. Haszprunar (1985a,b; 1987a, b; 1992) did extensive electron microscopic investigations on the osphradia of various molluscan groups, but not the Pectinidae. Such a study was later performed in *Placopecten magellanicus* and *Pecten maximus* (Beninger et al. 1995a). The structure consists of an eversible ridge with subjacent muscle fibres, (Fig. 3.35.2), and a dorsal tuft cilia region. The eversible character of the ridge may account for the confusion concerning the location of the osphradium in species in which it is not pigmented (see below). The ridge epithelium contains many secretory cells, which appear to produce neurosecretions which are transported along microtubules to the bases of the cells, where axons join the osphradial nerve (Figs. 3.35.3–3.35.5). In *Pecten maximus*, pigment granules are also secreted by these cells, giving the osphradium a distinct orange pigmentation (and hence a sure way of locating the structure!). The tuft epithelium appears sensory in structure, with both free nerve fibres and ciliated cells (Fig. 3.35.6) similar to those described by Haszprunar (1987a). No specialised cilia form is observed, and it is probable that the ‘paddle cilia’ previously reported as diagnostic features of the osphradium (e.g., Haszprunar 1985) are artefacts of hypotonic fixation (Beninger et al. 1995b).

Numerous functions have been proposed for the bivalve osphradium, reviewed by Haszprunar (1987a). This author concluded that the most probable function is that of chemoreception of a gamete release signal. The histological and ultrastructural data for *Placopecten magellanicus* and *Pecten maximus*, together with data on the innervation of the osphradium and the location of monoamines in *Pecten maximus*, led Beninger et al. (1995a) to support this view, proposing a dual function of both stimulus reception (for the sensory cells), and of serotonin production (for the secretory cells of the osphradial ridge), which is then axonally transported (Fig. 3.35.5) and stored in the accessory lobe of the parietovisceral ganglion (Fig. 3.36). The rate of serotonin production and storage could depend on approximate timing cues, such as cyclic temperature changes or even more proximate changes due to downwelling events (Bonardelli et al. 1996). Release of the stored serotonin would induce gamete release in the nearby gonad, allowing vitally-precise synchronisation, enhancing the probability of fertilisation within a population.

The nature of the stimulus is not yet known, but is presumed to be a substance contained in male ejaculate.

Figure 3.36. The proposed pathway for axonal transport of neurosecretions produced in the secretory cells of the pectinid osphradium (arrows). The dotted regions indicate sites of monoamine storage. Modified after Beninger et al. (1995).

3.8.2.5 Statoreceptors

Much of the remarkable early work concerning pectinid statoreceptors (Drew 1906; Buddenbrock 1915) was confirmed and extended in Barber and Dilly (1969). The terminology used by the earlier authors is rather more complex; they distinguish *statocysts*, or closed statoreceptor sacs, and *statocrypts*, or statoreceptors, which communicate with the external medium. In addition, they distinguish *statoliths*, or single endogenously-formed crystals, and *statoconia*, or multiple small crystals. Statoconia of exogenous origin (in the case of statocrypts) are termed *pseudostatoconia*. The statoreceptors of scallops have been termed both statocrypts and statocysts by these authors. Regardless of semantics, the statoreceptors of scallops show a marked asymmetry, the left one being more developed than the right one. Each statoreceptor consists of a sac-shaped sensory epithelium, and a fluid-filled lumen containing one or several crystals. The sensory cells are inappropriately called *hair cells*, due to the sensory cilia at their apical extremities. The left statoreceptor hair cells present up to 30.9 ± 2 type cilia each, with striated roots penetrating deeply into the cell body, whereas the right statocrypt hair cells only have about 10 such cilia. Each hair cell produces an axon at its basal extremity (Fig. 3.37). Both statoconia and statoliths have been reported in scallops (Drew 1906; Buddenbrock 1915; Barber and Dilly 1969). Buddenbrock (1915) believed the statoconia of *Pecten inflexus* to be exogenous, being predominantly formed of sponge spicules (which presumably enter via the statocystic canals) and cemented by mucus into a compact mass, whereas he reported other scallop species such as *Chlamys varia* to have true endogenous statoliths, the canal to the exterior being blind and vestigial (Buddenbrock 1915). The statoreceptor axons group to form the statocystic nerves leading to the cerebral ganglion, as mentioned previously.

The pronounced asymmetry of scallop statoreceptors may correspond to its sedentary life habit, with the animal always resting on the same valve (usually the right one). However, it should be noted that ablation of the statoreceptors in the scallop species studied by Buddenbrock (1915) does not affect the righting reflex. Furthermore, the vertical steering component of the swimming reflex is affected by removal of the left statoreceptor, though unaffected by removal of the right one (Buddenbrock 1915). The left statoreceptor may thus be an essential element in the control of the swimming reflex. This topic is covered in detail in Chapter 5.

3.8.3 Neurotransmitters and Neurohormones

Several different neurotransmitters have been partially identified in the scallop nervous system. The distribution of acetylcholinesterase and monoamine oxidase in the central nervous system of *Patinopecten yessoensis* indicates the presence of acetylcholine and a serotonin-like monoamine, respectively (Chang et al. 1984). A serotonin-like monoamine was also detected by Paulet et al. (1993) in the parietovisceral ganglion. Recent histochemical work has revealed the presence of FMRFamide (Phe-Met-Arg-Phe-NH₂) - like molecules in all of the ganglia of *Placopecten magellanicus* (Too and Croll 1995). Using HPLC, Pani and Croll (1995) detected the presence of the catecholamines

Figure 3.37. 3,4 dihydroxyphenylalanine, dopamine, norepinephrine, and epinephrine, as well as the indoleamine 5-hydroxytyptamine, in the ganglia, and in most organs of *Placopecten magellanicus*. The latter studies indicate that knowledge of pectinid and indeed bivalve neurophysiology, is quite embryonic at this stage. We are only now beginning to discover the types of neurotransmitters found in gross anatomical structures; precise mapping to the level of precision now available for the human nervous system is a seemingly distant goal.

The roles of the various bivalve neurotransmitters are even less well known. Serotonin has been implicated in the regulation of sodium transport (Dietz et al. 1984), gamete release (see Ram et al. 1997 for review), ciliary beat (e.g., Jørgensen 1976; Silverman et al. 1999), with cAMP mediation (Stommel and Stephens 1985), cardiac function (Welsh and Moorhead 1960) and probably also in the extremely ubiquitous and polyvalent function of mucus secretion (Lent 1974).

While all of the molecules mentioned above may function as neurotransmitters, it is equally likely that they also have roles as neurohormones. The existence of neurosecretory cells was demonstrated in all of the ganglionic concentrations of several bivalve species by Gabe (1955). Lubet (1955) showed the relationship between the secretory activity of these cells and the reproductive cycle of *Chlamys varia* and *Mytilus edulis*. In *Mytilus edulis*, the greatest concentration of such cells appears to be in the cerebral ganglia (Lubet and Mathieu 1982), from which a gonial mitosis stimulating factor has been isolated (Mathieu et al. 1988). Studies using organ cultures have shown that gametogenesis in *M. edulis* is influenced by nonspecies-specific neurosecretions of the cerebral ganglia (Lubet and Mathieu 1982). In addition, the gametogenesis of cultured *Chlamys opercularis* tissue may be triggered by *M. edulis* ganglia secretions (Allarakh 1979, cited by Toullec et al. 1988).

Since the experiments of Matsutani and Nomura (1982), it is known that serotonin stimulates the actual spawning in *Patinopecten yessoensis*. The same effect has also been obtained for a variety of other bivalves, including *Argopecten irradians* (Gibbons and Castanga 1984). Perikarya of serotonin-like monoamine-secreting neurons have been observed in the cerebral, pedal, and accessory ganglia of *Patinopecten yessoensis*, while serotonin-like, monoamine-secreting fibres derived mostly from the cerebro-visceral connective terminate in the acinal walls and gonoduct of the gonad (Matsutani and Nomura 1984, 1986). Beninger et al. (1995a) proposed that secretions formed in the scallop osphradium were monoamines axonally transported and stored in the accessory lobes of the parietovisceral ganglion; release to the gonad via the gonadal nerve would provoke gamete emission (Fig. 3.36).

In addition to neurosecretions involved in reproduction, the bivalve nervous system includes secretory neurons which regulate somatic growth. A nonspecies-specific growth factor isolated from the cerebral ganglia of *M. edulis* is active with *Pecten maximus* tissue, indicating that a similar secretion exists in pectinids (Toullec et al. 1988). A somatostatin-like substance has also been isolated from peripheral cells of the parietovisceral ganglion of *Pecten maximus* (Le Roux et al. 1987). Somatostatin-like receptor cells have been identified in the kidney (see Section 3.6.1) and in the digestive gland (Le Roux et al. 1987). Clearly, much further study needs to be done concerning the nature and roles of both neurotransmitters and neurohormones in bivalves, and notably in pectinids.

3.9 FOOT-BYSSAL COMPLEX

In contrast to mytilids (see Morse and Zardus 1997 for summary and references), relatively few studies have been performed on the foot and byssal complex of the Pectinidae. Nevertheless, a good account of the structure and function of this system may

be derived from the work of Mahéo (1968, 1969), Gruffydd (1978) and Gruffydd et al. (1979).

3.9.1 External Morphology and Development of the Foot-byssal Complex

The pectinid foot arises out of the antero-dorsal surface of the gonad and is roughly cylindrical in shape, terminating in a sucker-like formation called the sole (Drew 1906; Gruffydd 1978), or, more appropriately, the cornet (Pelseneer 1906; Mahéo 1969). The cornet is wedge-shaped in longitudinal section, the dorsal surface being more prominent than the ventral surface. The pedal groove, which runs along the mid-ventral portion of the foot, is enclosed except for a small portion, which is visible as a slight depression just behind the cornet (Fig. 3.38).

The pectinid foot is small compared to that of the Mytilidae; however, it may be more or less developed depending on the adult life habit and the importance of the byssal gland in different species. Most scallops begin their postlarval life as byssally-attached juveniles; some species retain this capability while others grow into free-living adults. In byssally-fixed species such as *Chlamys varia*, the very active foot can be extended out through the byssal notch between the valves. In species in which the adult is free-living, such as *Pecten maximus*, the adult foot is a degenerate structure, which plays no role in locomotion or in fixation. Other species in which the foot-byssal complex regresses in the juvenile stage include *P. jacobaeus*, *Chlamys islandica*, *C. squamosus*, and

Figure 3.38. Schematic illustration of the anatomical relationships of the foot and byssal gland of *Chlamys varia*. C. groenlandicus. In *Placopecten magellanicus* and other non-attached scallop species Drew (1906) suggests that the foot may be used to clean the labial palps and the anterior part of the gills, as observed in pearl oysters (*Pinctata* spp.). This interesting hypothesis merits verification.

3.9.2 Anatomy and Histology of the Foot-byssal Gland Complex

In most bivalves the foot is connected to the shell via an anterior and a posterior pair of pedal retractor muscles. In monomyarians, however, the anterior retractor muscles are generally absent, and in the Pectinidae only the left posterior retractor remains, being inserted on the left shell close to the dorsal margin of the adductor muscle. The degree of development of this muscle varies among species according to the degree of development of the foot, being rather well-developed in *Chlamys opercularis* and rudimentary in *Pecten maximus*.

The external covering of the foot consists of a typical pseudostratified ciliated epithelium (Mahéo 1969). Beneath this layer are found the glandular systems, nerve fibres from the pedal nerves, circular and longitudinal muscle fibres, and lacunar connective tissue filled with haemolymph (Fig. 3.40). The glandular systems, occupying nearly half the volume of the foot, consist of a protein gland, an enzyme gland, and a mucous gland.

3.9.2.1 The protein gland

The protein gland is the most voluminous gland of the foot-byssal complex. It is situated on both sides and above the pedal groove, and also extends into the proximal dorsal portion of the foot. In this region, the dorsal surface of the pedal groove becomes progressively folded, assuming an accordion-like appearance (Figs. 3.39, 3.40). The folds consist of connective tissue, and are simply called connective tissue folds or lamellae. The large (10–15 µm) glandular cells secrete a proteinaceous substance either directly into the pedal groove (distal portion), or across the connective tissue lamellae in the proximal portion of the foot. In this region, the secretions traverse the lamellae at their ciliated crypts, and are then swept into the pedal groove by the ciliary action of the epithelial cells lining the groove. Each crypt or trough of the lamellae secretes its own individual ribbon (Gruffydd et al. 1979). Gruffydd (1978) divides the protein gland into two components: the primary (lamellar) byssal gland, and the secondary (distal) byssal gland running along the pedal groove.

3.9.2.2 The enzyme gland

The enzyme gland consists of a thin layer of tissue situated below the protein gland, on either side of the pedal groove (Figs. 3.39, 3.40). It does not extend into the proximal portion of the foot. The secretions of this gland include a polyphenoloxidase (Mahéo 1969; Gruffydd 1978).

Figure 3.39. Schematic illustration of the glandular systems of the foot-byssal complex of *Chlamys varia*. BG1, primary byssus gland; BG2, secondary byssus gland; CTL, connective tissue lamellae; EGL, enzyme gland; MG, mucous gland; PG, pedal groove; PRM, pedal retractor muscle. 3.9.2.3 *The byssus*

The byssus is formed of a root from which extend several relatively thick ribbons, in contrast to the many thin threads of the Mytilidae (Mahéo 1969; Gruffydd 1978; Gruffydd et al. 1979). It is composed of complex proteinaceous molecules (Bubel 1984). The root is formed of 30–50 fibrous ribbons formed from secretions of the primary byssus gland (Gruffydd 1978; Gruffydd et al. 1979). These fibres are covered by a thin matrix of amorphous material at their proximal extremities. The proximal portions are thick and unstructured, whereas the distal portions are finely folded and the matrix covering becomes progressively thinner (Gruffydd et al. 1979). The ribbons are bound together by a fibrous sheath, secreted by the secondary byssus gland (Gruffydd et al. 1979).

3.9.3 Functioning of the Foot-byssal Complex

Prior to fixation, the foot extends out from the byssal notch in the shell and actively explores the surrounding substrates. The cornet then presses against a substrate, and several minutes later (4–10 minutes in *Chlamys varia*) the foot retracts, leaving a filament which fixes the animal to the substrate (Mahéo 1969). Throughout the period of extension, protein granules are secreted by the primary and secondary byssus gland and are swept into the pedal groove. The secretions are presumably tanned by the products of the enzyme gland, although it is not yet known exactly how the proteinaceous secretions are formed into distinct ribbons bounded by a sheath. The ciliary beating of the pedal groove epithelial cells probably acts to mix the aromatic proteins and the polyphenoloxidase, promoting tanning. Gruffydd et al. (1979) propose that incompletely-tanned ribbons are stored in a special pouch of the primary byssus gland, being moved into the pedal groove and stretched outward by ciliary action.

Once the ribbon is tanned and anchored to the substratum, the sides of the pedal groove curl outward along the short non-enclosed length, leaving a ribbon, which extends into the primary byssus gland. A new thread may then be put in place, more or less fused with the previous one by incomplete tanning. In the proximal region of the foot, the accumulation of untanned and partially-tanned ribbons forms the byssal root. The root is held in place by the continuous contraction of numerous muscle fibres. Prior to the swimming response, these muscles relax, separating the untanned portions of the ribbons from the primary byssus gland. The byssus then detaches and the animal is freed of its connection to the substrate (Mahéo 1969).

ACKNOWLEDGMENTS

Photographic assistance was kindly provided by A. Le Mercier and L. Blanchard. Assistance with electron microscopy of previously unpublished work was provided by Dr. G. Sinquin. Mad. O. Aumaille assisted with some lettering and reference checks. Funding during the preparation of the second edition of this chapter was provided by the Syndicat Mixte pour le Développement de l'Aquaculture aux Pays de la Loire, although not for this project.

Chapter 4

Scallop Adductor Muscles: Structure and Function

Peter D. Chantler

4.1 INTRODUCTION

Scallop aquaculture owes its commercial success to a global appreciation of the gastronomic delights of this animals' adductor muscles. For this reason alone, these muscles would have been considered worthy of study. Early physiologists were also impressed by the high muscle to body weight ratio, the apparent purity of the fibres and the clarity of function of the two main adductor muscles. More recently, biochemists have shown that these muscles possess a mode of regulation that is closely related to mechanisms found both in vertebrate smooth muscles and in non-muscle cells; furthermore, because scallop myosins have been shown to possess unique physical properties making them ideally suited for biochemical manipulation, they remain a key model for studies on the function and regulation of muscle contraction.

Typically, scallops possess two adductor muscles (Fig 4.1a). The phasic adductor, often the most dominant feature in the body of the animal, is the muscle sought by gourmets and gourmands alike. It is cross-striated and facilitates fast, repetitive opening and closing of the valves; contraction of this muscle causes a rapid ejection of water from the mantle cavity, enabling the animal to swim by jet propulsion (see Wilkens 1991) powered, in the main, by anaerobic metabolism (De Zwaan et al. 1980). The smaller tonic adductor is more commonly known as the catch muscle. It is a smooth muscle, lacking cross-striations; its slower contraction is capable of generating considerable force, keeping the animal's hinged shell closed for long periods of time with little expenditure of energy. In most scallops, the two types of adductor muscle lie closely apposed to one another and there is often a gradual transition of fibre type from one muscle to the next.

Molluscan muscles, like vertebrate skeletal muscles, contract by a sliding filament mechanism, the thin filaments sliding past the thick filaments through the cyclical action of crossbridges extending out from the myosin-containing thick filament to make contact with the actin-containing thin filaments (Fig. 4.1b; Hanson and Lowy 1959; Hanson and Lowy 1960). Our knowledge of the structure and biochemistry of scallop adductor muscles has largely been obtained from four species: *Pecten maximus*, from the shores of Britain, *Argopecten irradians* and *Placopecten magellanicus*, from the eastern seaboard of the United States, and *Patinopecten yessoensis* from the coastal waters off Japan.

The interested reader may supplement the following account with reviews which cover the regulation of contraction by the scallop striated adductor muscle (Szent-Gyorgyi and Chantler 1994), the comparative structure and biochemistry of molluscan muscles

Figure 4.1 A. Photograph of *Placopecten magellanicus* after removal of all organs and tissues surrounding the adductor muscles. The striated (S) and catch (C) adductor muscles were left *in situ* and allowed to extend overnight under sustained pressure from the hinge (seen to the right of the muscles) in a solution containing 50% ethylene glycol. The catch muscle, which is the smaller of the two adductors, is seen to advantage in this perspective. B. Schematic of sarcomeric structure as seen in a typical striated muscle fibre. Longitudinal views through two sarcomeres (seen on the left) are compared with cross-sectional views through the A-band (seen on the right) at three different sarcomeric lengths. a). Sarcomeres at rest length (l_0). b). Sarcomeres stretched to $1.3 l_0$. c). Sarcomeres contracted to $0.6 l_0$. The locations of the A-band, I-band, H-zone, M-band and Z-line are indicated. Note the decrease in spacing between thin and thick filaments as a function of increasing sarcomere length. Adapted from "Muscles, molecules and movement", by J.R. Bendall (1969). Heinemann Educational Books Ltd.

(Chantler 1983), the structure of, and transmission across, molluscan neuromuscular junctions (Muneoka and Twarog 1983; Nicaise and Amsellem 1983), the general structure of muscle (Craig 1994) and the mechanism of contraction and motor function (Cooke 1997; Howard 1997; Geeves and Holmes 1999).

4.2 STRUCTURE OF THE STRIATED ADDUCTOR MUSCLE

4.2.1 Fibre Microanatomy

In scallops, the large adductor muscle is cross-striated. Cross-striations can be seen by light microscopy but are most clearly visualised by electron microscopy which reveals the sarcomeric structure, the alignments of thick and thin filaments and the Z-lines (Fig. 4.2). Each muscle cell of the scallop striated adductor muscle is relatively small and ribbon-like compared to vertebrate skeletal muscle cells. Individual muscle cells are shorter than the length of the muscle; for example, in *Argopecten irradians* the average fibre length for a muscle length of 2 cm was calculated to be close to 650 μm (Nunzi and Franzini-Armstrong 1981). The ribbon-like character of the muscle cells is best seen in cross-sections (Fig. 4.2a) where typically, the short and long diameters are of the order of 1 and 10 μm , respectively (Morrison and Odense 1974; Millman and Bennett 1976; Nunzi and Franzini-Armstrong 1981). Each cell contains a single, centrally-placed myofibril, sometimes partially or completely divided into submyofibrils (Nunzi and Franzini-Armstrong 1981) and is bounded by a surface membrane. There are no invaginations of this membrane that could be termed a transverse tubular system in this muscle (Sanger 1971; Nunzi and Franzini-Armstrong 1981), the small fibre diameter probably rendering such a system unnecessary. Nevertheless, there is a complex sarcoplasmic reticulum (Sanger 1971; Morrison and Odense 1974), the cisternae of which form peripheral couplings (junctional feet) with the surface membrane (Fig. 4.3), these structures being similar to those found in vertebrates (Nunzi and Franzini-Armstrong 1981). The composition of the sarcoplasmic reticulum membrane from *Placopecten magellanicus* appears to comprise a near-crystalline array of dimer ribbons of Ca^{2+} -ATPase molecules (Castellani and Hardwicke 1983; Castellani et al. 1985). Between cells, both in series and in parallel, are junctions similar to the *fasciae adherentes* of the intercalated discs of vertebrate myocardium (Fig. 4.3; Nunzi and Franzini-Armstrong 1981). Gap junctions are also fairly common.

In contrast to vertebrate fast twitch muscles, there is no evidence of M-bridges holding adjacent thick filaments together at the centre of a sarcomere. Each "A"-band within a sarcomere typically has a somewhat ragged edge (Fig. 4.2e), possibly because of this absence of M-bridges necessary to hold the structure together and/or the presence of adjacent thick filaments of differing length. Twitchin-like mini-titins are present in the A-bands of both striated and smooth adductor muscles (Vibert et al. 1993) but it is not clear that these 0.2 μm long proteins connect the thick filaments to the Z-lines, as is found in vertebrate muscles. Indeed, the lateral alignment of Z-lines in adjacent myofibrils is very easily disturbed. Each myosin-containing thick filament (~20 nm backbone diameter and 1.7 μm in length in the Atlantic scallops) (Morrison and Odense 1974; Millman and

Figure 4.2. Structure of the striated adductor muscle (*Pecten maximus*). a). Low magnification transverse section showing the elongated profile of the muscle fibres and the appearance of the filaments at different regions in the sarcomere. B, bare zone; H, part of the H-zone where the thick filaments show projections; I, I-band; O, region where the thin and thick filaments overlap. b). High-magnification transverse section of the bare-zone region of the sarcomere. c). High-magnification transverse section through the overlap region. d). High-magnification transverse section through that part of the overlap region where the thick filaments taper. Magnification scale bars are seen in a) and c); magnifications of images seen in b), c) and d) are the same. Micrographs reproduced, with permission of the publisher, from Millman and Bennett (1976).

Figure 4.2e. Structure of the striated adductor muscle (*Pecten maximus*). e). Longitudinal section through ribbon-like muscle fibre. Magnification scale bars is included. Micrographs reproduced, with permission of the publisher, from Millman and Bennett (1976).

Bennett 1976) is packed in a hexagonal array, 60 nm from its neighbour, and is surrounded by approximately 12 actin-containing thin filaments, each 7–9 nm in diameter (Fig. 4.2c, d). The core of striated adductor thick filaments contains paramyosin (approximately 7% of the thick filament by weight) (Hardwicke and Hanson 1971; Levine et al. 1976; Millman and Bennett 1976) but this amount is small by contrast with thick filaments from the smooth adductor muscles.

4.2.2 Actin and Thin Filament Structure

The basic structure of the scallop striated adductor thin filament is very similar to that of its vertebrate counterpart. However, there is still controversy as to the amount and functionality of troponin in these filaments. Notwithstanding the variation in the amounts of troponin present within muscles of different molluscan species, the underlying structure of the thin filament is one with which we are familiar.

Figure 4.3. a). A fascia adherens joining two striated adductor muscle cells from *Argopecten irradians* in series (between arrows). Notice the dense material filling the junctional gap and the intermediate dense line between the two cell membranes. In the lower half of the image, a grazing view of the sarcoplasmic reticulum illustrates its anastomosing configuration. Cisternae formed at the crossover points (asterisks) form peripheral couplings with the surface membrane. b). Detail of a peripheral coupling. A strip of extracellular space crosses the image from left to right and the peripheries of two fibres are above and below. The junctional surface of a sarcoplasmic reticulum cisterna (SR) is coupled to the surface membrane by regularly spaced feet (arrows). Scale bars indicate the magnification. Micrographs reproduced, with permission of the publisher, from Nunzi and Franzini-Armstrong (1981).

Thin filament structure is based on the actin filament (Fig. 4.4). Tropomyosin, found in all molluscan thin filaments, is located within the major grooves on either side of the actin filament. Troponin, in those muscles where it is found, is located with a 38 nm periodicity along each thin filament, where it forms attachments to both tropomyosin and actin.

The structure of filamentous actin (F-actin) is well-known, considerable information coming from studies on scallop actin (Hanson and Lowy 1963; Millman and Bennett

Figure 4.4. A. High-magnification micrograph of purified scallop F-actin, partially decorated with scallop myosin heads (S-1) (only a few S-1 molecules are visible). Scale bar indicates magnification. B. High-magnification micrograph of purified scallop F-actin fully decorated with scallop S-1, illustrating arrowhead formation. Scale bar indicates magnification. C. Diagram illustrating the structure of an actin helix, composed of 28 subunits in 13 turns of the genetic helix, in association with tropomyosin and troponin. Micrographs reproduced, with permission of the publisher, from Vibert and Craig (1982). Diagram reproduced, with permission of the publisher, from Squire and Morris (1998).

1976; Craig et al. 1980; Egelman et al. 1982; Vibert and Craig 1982; Egelman et al. 1983). F-actin is composed of a double string of globular subunits (G-actin protomers, each of 42 kD molecular weight), 9 ± 1 nm in diameter, wound as a right-handed helix about a central axis (Fig. 4.4c). This structure may be described as a shallow helix of pitch 76.0 nm with crossovers every 38.0 nm along the filament – as determined for thin filaments from *Pecten maximus* and *Placopecten magellanicus*, using X-ray diffraction techniques (Millman and Bennett 1976). The axial spacing of subunits in each strand of the helix is 5.5 nm, and there are 13–14 subunits per strand in one turn of each long-pitch helix. The two chains are staggered, with respect to each other, by about half a subunit. Alternatively, F-actin structure may be described in terms of the “one-start”, short-pitch (5.9 nm), left-handed “genetic” helix, formed as one moves about a unidirectional axis

along a line passing through all protomers in turn (Fig. 4.4c). In the case of scallop F-actin, 28 actin protomers are present in 13 turns of the genetic helix (2.1538 protomers per turn) (Egelman et al. 1982). Despite this apparent order, individual subunits in the F-actin helix appear to exhibit considerable angular displacements with respect to adjacent subunits ($\pm 10^\circ$), imparting a random variable twist to the filament which manifests itself as a variation in pitch along the length of an individual filament (Egelman et al. 1982; Egelman et al. 1983); this rotation is thought to facilitate the interaction of actin with a great variety of actin-binding proteins.

F-actin can be depolymerised *in vitro* into its individual globular subunits by dialysis against ATP and trace amounts of calcium or magnesium, at low ionic strength. G-actin, so-formed, possesses one molecule of ATP and one tightly bound divalent cation per molecule, both of which are freely exchangeable. Although the crystal structure of G-actin has not been obtained directly, the structure of the actin monomer has been determined at atomic resolution through crystallisation as a complex with DNase I (Kabsch et al. 1990), gelsolin (McLaughlin et al. 1993) or profilin (Schutt et al. 1993) (Fig. 4.5a). The molecule displays two distinct domains separated by a cleft within which the nucleotide and divalent cation are bound. Each domain is further divided into a pair of subdomains, numbered from I through IV (Fig. 4.5a). Subdomain I contains both the amino and carboxyl termini of the molecule, as well as the primary site for interaction with myosin.

The particular isoform of actin found in scallop adductor muscles is β -actin (Margulis et al. 1982; Chantler 1983); this isoform appears to be distributed throughout all scallop tissues (Hue et al. 1989). Actin isoforms are distinguished by the identity of the four N-terminal amino acid residues (Vandekerckhove and Weber 1979); e.g., the N-terminal sequence from *Pecten maximus* is acetyl-Asp.Asp.Glu.Val... (Vandekerckhove and Weber 1984). Actin sequences are highly conserved: scallop actin and vertebrate actins differ in less than 6% of their residues; e.g., *Patinopecten yessoensis* actin has 21 (out of 374) amino acid substitutions with respect to vertebrate skeletal muscle actin, most changes occurring within subdomains I and III (Khaitlina et al. 1999). These structural differences confer subtle functional differences: scallop actin polymerises less readily than its vertebrate counterpart (Khaitlina 1986) and exhibits differing proteolytic susceptibility (Khaitlina et al. 1999) and antigenicity (Hue et al. 1988; Hue et al. 1989).

An increase in ionic strength causes G-actin to polymerise into F-actin, this process being accompanied by the hydrolysis of ATP to yield bound ADP. F-actin cannot be crystallised but its structure is amenable to analysis at low resolution by the combined techniques of optical diffraction and three dimensional reconstruction, which have been applied to the scallop thin filament (Craig et al. 1980; Vibert and Craig 1982; Egelman et al. 1983). More recently, the orientation of actin monomers within the filament structure has been established by modelling monomer structure against data obtained from fibre X-ray diffraction patterns from aligned gels of actin filaments (Holmes et al. 1990; Lorenz et al. 1993). In this structure (Fig. 4.5b), the long axis of the actin monomer passes through both domains and is arranged so that it is perpendicular to the axis of the F-actin filament, as originally envisaged from optical reconstructions (Egelman et al. 1983). Subdomains III and IV are shown to be positioned close to the helix axis and interact with subdomains

Figure 4.5. A. The structure of an actin monomer. This structure is shown as a wire-frame structure on which the α -carbon backbone has been highlighted. It is drawn in RasMol (version 2.5) using coordinates downloaded from the Protein Data Bank, Research Collaboratory for Structural Bioinformatics, Rutgers University (accession code 2BTF) for actin-profilin (Schutt et al. 1993); profilin has been rendered invisible so that the structure of the actin monomer can be seen clearly. α -helices are coloured green; component chains of β -sheets are coloured orange; the remainder of the α -carbon backbone is coloured grey. This globular structure is composed of four lobes (I, II, III and IV), II and IV being separated by a deep nucleotide binding cleft with ATP (red) positioned at the base. Note the position of Tyr-69 (blue), a residue which, when modified with a bulky group, affects the dynamic interaction between monomer and polymer (Chantler and Gratzer 1975). Both the N-terminus (yellow) and C-terminus (magenta) are located within lobe I. B. Ribbon structure of the actin monomer seen in A placed into a 13/6 helix (Holmes et al. 1990), the final structure being the best fit model for X-ray diffraction data from gels of oriented actin filaments. C. and D. Ribbon structures of the actin filament model seen in B together with tropomyosin (red) as seen in orthogonal views (Lorenz et al. 1995). Figures for B, C and D kindly provided by Prof. Ken Holmes and reproduced with permission of the publishers.

III or IV of adjacent actin monomers within the filament (Holmes et al. 1990). Small changes in the relative positions of subdomains II and IV occur upon polymerisation (Lorenz et al. 1993), accounting for the conformational changes known to occur when a G-actin monomer becomes a protomer in the F-actin structure, as deduced earlier by both functional (Offer et al. 1972; Chantler and Gratzer 1976) and spectroscopic (Higashi and

Oosawa 1965; Chantler and Gratzer 1975) techniques. Further conformational changes to actin protomers may be elicited upon myosin binding to F-actin when the latter is bound to tropomyosin (Tobacman and Butters 2000).

Tropomyosin has been found in all muscles without exception and is located within the two long-pitch grooves of the actin filament (Figs. 4.4c, 4.5c, d). It is a long, thin molecule, 41 nm in length and 2 nm in diameter (Cohen et al. 1971a), 66–70 kDa molecular weight (Woods 1969) and composed of two polypeptide chains arranged in parallel with each other, with no axial stagger, as α -helical coiled coils (Cohen and Holmes 1963; Lehrer 1975; Stewart 1975; Phillips et al. 1979). Tropomyosin can interact with seven actin protomers along each long-pitch helical groove of F-actin; it exhibits a 14-fold pseudo-repeat of charged residues which has led to suggestions that it can bind to each of the seven protomers at two different sites (Parry 1975; Stewart and McLachlan 1975; Hitchcock-DeGregori et al. 1990). Two different cDNAs, coding for the same tropomyosin sequence but possessing different polyadenylation signals, have been characterised from *Placopecten magellanicus* striated adductor muscle (Patwary et al. 1999). Scallop adductor muscles, similar to vertebrate skeletal muscles, express seven actin monomers for every tropomyosin (Chantler and Szent-Gyorgyi 1980). Using techniques of modelling fibre diffraction patterns similar to those described for actin above, the location of tropomyosin within the actin groove has been obtained with high precision (Lorenz et al. 1995) (Figs. 4.5c, d). Furthermore, direct evidence for the steric blocking model of tropomyosin action has been visualised by three-dimensional reconstruction of *Limulus* thin filaments, in the presence and absence of calcium (Lehman et al. 1994). The simplest interpretation is that tropomyosin can occupy either of two stable positions, one preventing access of myosin heads to subdomain I of actin (blocking state, observed in the absence of calcium) or, by moving deeper into the long-pitch actin groove, another stable position that facilitates strong, stereospecific myosin interaction (open state, observed in the presence of calcium) (Rayment et al. 1993b; Lehman et al. 1994). Other, more complex three-state interpretations are also possible and may be required to explain all aspects of the available data (Squire and Morris 1998; Tobacman and Butters 2000). Adjacent tropomyosin molecules within a groove of the long axis of the thin filament overlap each other in a head to tail fashion by nine residues (Phillips et al. 1979), a feature of possible significance for long range cooperativity in the thin filament (Brandt et al. 1984; Lehrer and Geeves 1998; Tobacman and Butters 2000).

Although scallop striated adductor tropomyosin may differ from its better known vertebrate counterpart in detail (Woods and Pont 1971; Woods 1976), the overall impression is that these striated muscle tropomyosins are very similar molecules. Many vertebrate muscles possess polymorphic forms of tropomyosin (Perry 1994). Despite evidence for more than one tropomyosin gene in *Placopecten magellanicus* (Patwary et al. 1999), a single isoform appears to be present within the striated adductor muscles of *Patinopecten yessoensis* and *Chlamys nobilis* (Ishimoda-Takagi et al. 1986; Ishimoda-Takagi and Kobayashi 1987). While it is easy to understand the role of tropomyosin in those scallop muscles possessing troponin, where it is essential for the steric blocking mechanism of thin filament-linked regulation, its role in scallop striated adductor muscles

subject to thick filament-linked regulation alone is still not fully understood other than in its capacity of placing constraints on the rigidity and flexibility of the thin filament.

Troponin, the key regulatory complex isolated from muscles exhibiting thin filament-linked regulation, is composed of three subunits: troponin C (calcium binding subunit, 18–20 kDa), troponin I (inhibitory subunit, 19–40 kDa) and troponin T (tropomyosin binding subunit, 31–52 kDa). In such muscles, troponin is found associated with the thin filament in a stoichiometric ratio to tropomyosin. The individual troponin subunits are usually considered to be present in the ratio C:I:T = 1:1:1 (Potter 1974) although a ratio of C:I:T = 1:2:1 has been suggested for both vertebrate (Sperling et al. 1979) and invertebrate (Lehman et al. 1976; Ojima and Nishita 1986a; Ojima and Nishita 1992) muscles. In native thin filaments troponin attaches at regular intervals of 38.5 nm (Ohtsuki et al. 1967; Ebashi et al. 1969; Ohtsuki 1974; Ohtsuki 1975), the repeat being determined primarily by the elongated troponin T subunit (Phillips et al. 1979) (Fig. 4.4c). Several detailed reviews of troponin and its role are available (e.g., Perry 1994; Squire and Morris 1998).

As noted earlier (Chantler 1991), functional assays of scallop myofibrils, actomyosin (Lehman and Szent-Gyorgyi 1975) and fibres (Simmons and Szent-Gyorgyi 1978) have indicated a complete absence of thin filament regulation in striated adductor muscles from some scallops (e.g., *Placopecten magellanicus*). Consequently, the many reports of the existence of troponin in molluscan muscles have been regarded as somewhat problematic. The presence of troponin in molluscan muscles is variable and species-specific (Chantler 1983) but the case in favour of dual regulation in some adductor muscles has been made stronger in recent years. Whereas some striated adductor muscles appear to possess near normal levels of troponin (e.g., *Argopecten irradians*) (Goldberg and Lehman 1978; Lehman 1983a) others appear to possess only trace amounts (e.g., *Placopecten magellanicus*) (Szent-Gyorgyi 1976; Lehman 1981). Whole troponin has been isolated from the striated adductor of *Chlamys nipponensis akazara* and *Patinopecten yessoensis* (Ojima and Nishita 1986a; Ojima and Nishita 1992); striated adductor troponin I from *Argopecten irradians* hybridises with other vertebrate troponin subunits to form functional complexes (Goldberg and Lehman 1978) and antibodies to *Argopecten irradians* troponins I and C stain myofibrils from the same muscle with a 38 nm periodicity (Lehman 1981; Lehman 1983a). Amino acid sequences of troponin C from the striated adductor muscles of the Ezo-giant scallop, *Patinopecten yessoensis* (Nishita et al. 1994) and the Akazara scallop, *Chlamys nipponensis akazara* (Ojima et al. 1994) have been determined and shown to exhibit low (<30%) homology with their vertebrate counterparts; only one (site IV) of the four EF-hand motifs found in vertebrate skeletal muscle troponin retained calcium-specific binding functionality. Sequences of troponin I (Tanaka et al. 1998) and troponin T (Inoue et al. 1996) have also been obtained from the Akazara striated adductor and also shown to exhibit minimal (<30%) homology with vertebrate troponin subunits. Recently, the complete gene for troponin C from the striated adductor of *Patinopecten yessoensis* has been obtained (Yuasa and Takagi 2000) and shown to lack a fourth intron, found in vertebrates, a feature shared with *Drosophila* troponin C and calmodulin. However, even in the most favourable circumstances, scallop thin filament-linked calcium activation rarely achieves greater than a four-fold activation and elevated levels of magnesium are usually required for functional demonstration

(Goldberg and Lehman 1978; Lehman 1983b; Ojima and Nishita 1986b). In reconstitution experiments using *Patinopecten* striated adductor muscles, only readdition of light-chain was able to depress the actin-activated MgATPase rate in the absence of calcium (Shiraishi et al. 1999), the feature which most workers correlate with regulation; readdition of troponin C only restored the depressed activated rates to their intact values (Shiraishi et al. 1999). So, while some striated adductor muscles may exhibit dual-regulation it remains plausible that much of this troponin has little functional value and may represent vestigial components, molecular survivors of an earlier regulatory system superseded by the advent of regulatory myosins (Chantler 1983).

4.2.3 Thick Filament Structure

In order for muscle cells to achieve reliable, repetitive contractions, myosin molecules are organised into remarkable bipolar assemblages known as thick filaments. While the structure of striated muscle thick filaments is dictated to a large extent by associations between adjacent myosin tails, the heads being exposed on the thick filament surface, one must not ignore the contribution of paramyosin to molluscan thick filament structure, even though it is relatively low in the striated adductor (<7% by weight) (Szent-Gyorgyi et al. 1971; Levine et al. 1976). Thick filaments possess a central bare zone (Fig. 4.6a) where the myosin molecules are packed in an antiparallel manner. Farther away from the bare zone, on either side of it, myosin molecules are packed in a parallel arrangement. Short, beaded rods known as end-filaments have been observed to protrude from the tapering extremities of scallop thick filaments (Vibert and Castellani 1989).

Using optical diffraction and computer image reconstruction of relaxed thick filaments isolated from the striated adductor of *Placopecten magellanicus*, it has been possible to obtain direct information on thick filament structure in this muscle (Vibert and Craig 1983). Although the thick filaments taper towards their ends, there is a substantial constant region on which imaging techniques can be relied upon to give precise data. Order is replaced by disorder when calcium is added to the relaxed filaments, bringing about activation (Vibert and Craig 1985; Frado and Craig 1989). Image analysis of electron micrographs of relaxed scallop thick filaments revealed seven sets of surface projections at any one level (Vibert and Craig 1983) (Fig. 4.6c), a finding that has been substantiated further by rapid freezing and freeze-substitution techniques (Craig et al. 1991) and by helical reconstruction of frozen-hydrated scallop myosin filaments (Vibert 1992). Six or seven sets of surface projections had also been predicted earlier from X-ray diffraction studies of this muscle (Wray et al. 1975). Projections were found to lie close to the thick filament surface, extending along it axially, yet slewing slightly around the filament in an ordered array comprising seven long-pitch helices (Figs. 4.6b, c) (Vibert and Craig 1983; Levine 1993). Each surface projection is now thought to represent two heads arising from adjacent myosin molecules on adjacent crowns (Fig. 4.6b-III), which are in close association and related by an approximate two-fold rotation axis; the overlaps are arranged along the seven long-pitch helices (Vibert and Craig 1983; Levine et al. 1988; Levine 1993; Padron et al. 1997). The interaction between adjacent myosin heads

Figure 4.6. A. Electron micrograph of a negatively stained image of a thick filament isolated from the striated adductor muscle of *Placopecten magellanicus* in the relaxed state. Bar represents 0.1 μm . 14.5 nm periodicities are indicated (white bars). End-filaments are also indicated (black arrow). B. Interpretative diagram showing three plausible arrangements (I-III) of myosin heads on the surface of relaxed scallop striated adductor thick filaments taking account of the results of crosslinking experiments using bis₂₂ATP (Levine 1993). The bare zone is toward the bottom of the filament. Underlying heads are shaded except where overlapped. In I, heads are splayed circumferentially, overlapping adjacent heads within the same crown. In II, heads from each myosin molecule are not splayed. In III, heads are splayed axially along each of seven helices, leading to an overlap of adjacent heads from molecules within adjacent crowns; the latter is considered the most likely situation. C. Cross-section through the scallop thick filament seen in A as determined by three-dimensional reconstruction techniques, demonstrating the seven-fold symmetry of myosin heads at any crown. In this diagram, several sections covering a 14 nm axial extent (one crossbridge level), have been superposed. Material reproduced, with permission of the publisher, from Vibert and Craig (1983) (A and C) or from Levine (1993) (B).

along ordered helical tracks may be similar to that envisioned by Offer and Knight (1996) on isolated myosin molecules, and is responsible for stabilisation of the ordered, relaxed structure (Padron et al. 1997). As with most myosin thick filaments, sets of crossbridge projections indicate an axial periodicity along the filament of some 14.5 nm (Fig. 4.6a). The bare zone in these filaments was found to be 140 nm in length and the filaments had an overall length of 2.0 μm . This indicates 64 levels of crossbridges in each half of the thick filament and approximately 900 myosin molecules per filament. Fourier transforms calculated from images of the constant region confirmed the presence of this well-defined helical surface lattice and allowed precise measurement of the 48.0 nm right-handed helical pitch, consistent with that expected for a 7-start helix.

Realisation of the importance of head-head interactions has been key to establishing an atomic model of thick filament structure (Padron et al. 1997) but a detailed understanding of how myosin tails are arranged within the filament has yet to be achieved. Paramyosin-rich filaments are thought to possess a thin layer of myosin molecules wrapped around a dense paramyosin core (see below). However, in thick filaments from scallop striated muscle, where the molar ratio of paramyosin to myosin is less than 10%, it is unlikely that paramyosin is arranged as a central core. X-ray diffraction patterns from live scallop muscle do not exhibit reflections characteristic of the typical paramyosin 72.5 nm period (Wray et al. 1975; Millman and Bennett 1976). When native thick filaments, extracted from either *Argopecten* or *Placopecten* striated muscle, are exposed to low ionic strength, their structures fray into subfilaments, each approximately 10 nm in diameter (Vibert and Castellani 1989; Castellani and Vibert 1992); the most likely number of subfilaments per thick filament is seven. Treatment of native or frayed thick filaments with antibodies that recognise paramyosin provided no indication of paramyosin localisation, implying that paramyosin epitopes remain inaccessible even when subfilaments are exposed (Castellani and Vibert 1992). It is possible, therefore, that paramyosin is located at the core of each subfilament; indeed, each subfilament may in turn be composed of sub-subfilaments arranged in groups around a subfilament paramyosin core (Castellani and Vibert 1992). The exact arrangement remains unknown but it is possible that paramyosin could be restricted to a region on either side of the bare zone. In support of this, a 29 nm periodicity (corresponding to one of the molecular displacements found in paramyosin crystals) has been found to flank the bare zone by 150 nm in either direction (Vibert and Craig 1983). Alternatively, this could represent a periodic disturbance within myosin heads displayed on the surface of the filament (Wray et al. 1975). One consequence of the underlying subfilament structure within the thick filament backbone would be to cause individual crossbridges in relaxed muscle to take up precise yet varied orientations with respect to the filament axis, depending upon the particular rotational symmetry, thereby offering an explanation as to why filaments of muscles from different species that exhibit different rotational symmetries, helical symmetries and diameters possess crossbridges that appear to lie at similar radii from the filament centre (Wray et al. 1975; Wray 1979; Maw and Rowe 1980; Luther et al. 1981; Trinick 1981; Wray 1982).

Twitchins, or mini-titins, molecules in the size range 600–800 kDa, have been isolated from both *Placopecten* striated and smooth adductor muscles (Vibert et al. 1993).

Antibodies raised against scallop mini-titins localised the protein to the A-band, especially at the A-I junction. Mini-titins are giant kinases belonging to the immunoglobulin superfamily of which vertebrate titin and nematode twitchin are related members; antibodies to twitchin cross-react with scallop mini-titin (Vibert et al. 1993). Whereas titin is a much larger protein and extends throughout the I-band, connecting each thick filament to the Z-band (Trinick 1992), the restricted yet varied distribution of mini-titins currently limits our understanding of their function (but see below). Because insect muscle mini-titins connect the Z-band with the A-band (Nave and Weber 1990), it remains possible that the size distribution determined for scallop mini-titins is a gross underestimate (as a consequence of proteolysis or shearing during preparation) and that the intact structure could extend throughout the I-band to the Z-band, allowing mini-titins to act as shock absorbers by suspending thick filaments in the middle of the sarcomere. It remains unclear as to whether mini-titin is localised within the end-filaments, which protrude from the tips of thick filaments (Vibert et al. 1993) as originally suggested (Vibert and Castellani 1989) or is more extensive. Antibodies to twitchin kinase, a specific domain of the twitchin molecule, label scallop mini-titin close to the M-band. As noted above, scallop thick filament assemblies do not show any features which would correspond to the M-bridges seen in vertebrate skeletal muscle (Millman and Bennett 1976).

4.3 STRUCTURE OF THE SMOOTH ADDUCTOR MUSCLE

4.3.1 Fibre Microanatomy

The catch adductor muscle exhibits two major features which characterises it as a smooth muscle: firstly, it lacks striations and secondly, it possesses numerous dense bodies, both throughout the sarcoplasm and peripherally, which take the place of the missing Z-bands and provide anchoring sites for actin filaments. Additionally, this muscle exhibits a high proportion of paramyosin to myosin (2–10:1 by mass) and demonstrates the physiological property of catch; it is therefore categorised as a “paramyosin smooth” muscle (Hanson and Lowy 1960; Chantler 1983).

The scallop smooth adductor muscle has some similarities to the striated adductor. For example, the sarcoplasmic reticulum possesses the same components (Fig. 4.7), though both longitudinal tubules and cisternae are said to be less numerous (Nunzi and Franzini-Armstrong 1981). Intercalated discs and *fasciae adherentes* are also present. Like the striated adductor, the cells are also small, possessing a single fibril at the centre. In cross-section, however, the profile is more rounded (Fig. 4.7a), measuring about 3 x 5 μm in the case of *Argopecten irradians* (Nunzi and Franzini-Armstrong 1981). The average fibre length in this muscle was calculated to be close to 375 μm (Nunzi and Franzini-Armstrong 1981). Cross-sections through the smooth adductor reveal a variety of thick filament diameters: this is because individual thick filaments, arranged parallel to the fibre axis yet possessing no lateral alignment, are long and taper substantially towards their ends. The widest part is found throughout the centre of the filament, including the region comprising the bare zone. Mean filament diameters, measured in the smooth

Figure 4.7. Scallop (*Placopecten magellanicus*) smooth adductor muscle. a). Low-magnification transverse section through catch adductor muscle fibres illustrating the variable diameter of thick filaments seen in a single cross-section, regions rich in thin filaments, a number of peripheral dense bodies as well as invaginations and vesicles of the sarcoplasmic reticulum. Micrograph courtesy of Dr. Clara Franzini-Armstrong. b). Longitudinal section through two adjacent smooth muscle fibres. Thin filaments are attached to elongated dense bodies both within the fibre and at the periphery (arrows). Elements of the sarcoplasmic reticulum are less numerous than in the striated portion, but have similar longitudinal profiles and peripheral cisternae (asterisks). Scale bars represent 1 μm . Micrograph reproduced, with permission of the publisher, from Nunzi and Franzini-Armstrong (1981).

adductors of the Atlantic scallops, peak in the range 20–50 nm (Philpott et al. 1960; Morrison and Odense 1974) though individual filaments may have diameters in excess of 100 nm (Elliott and Bennett 1982; Matsuno et al. 1996). Although it is generally accepted that paramyosin smooth filaments are very long (Fig. 4.7b), it would appear that no direct measurements have been made using filaments from scallop smooth adductor muscles. The anterior byssus retractor muscle (ABRM) of *Mytilus edulis* is often considered to be analogous to that of the scallop smooth adductor muscle (Nunzi and Franzini-Armstrong 1981) albeit with filaments having a larger average mean diameter (60–70 nm) (Sobieszek 1973). Here, the thick filaments have been estimated as being 20–30 μm in length (Lowy and Hanson 1962; Sobieszek 1973) and this is probably a reasonable guesstimate of filament length in the scallop smooth adductor. It may be noted that there is no necessary correlation between filament length and filament thickness (Nicaise and Amsellem 1983).

Figure 4.7a shows that in those regions of the cell possessing thick filaments, the filaments are approximately equally spaced from their neighbours, each surrounded by a halo of thin filaments. Nevertheless, it is clear that there are a number of regions in any cellular cross-section that are completely devoid of thick filaments and which possess huge numbers of thin filaments. It is possible that these areas represent regions adjacent to, but not coincident with, the dense bodies onto which the thin filaments are anchored. These dense bodies are fusiform structures, their shape readily envisioned by comparing their cross-sections (Fig. 4.7a) and longitudinal sections (Fig. 4.7b). Their sizes (1–2 μm long; 0.1–0.3 μm diameter) are comparable to those of dense bodies seen in the ABRM (Twarog 1967a; Sobieszek 1973). By analogy with the ABRM, 60–80 thin filaments will attach to opposite sides of each single dense body located in the body of the cell (Sobieszek 1973); peripheral dense bodies, attached to the sarcolemma in some way, only allow thin filament attachment on the cytoplasmic side.

4.3.2 Thin Filament Structure

Thin filaments from scallop smooth adductor muscles would appear to be very similar in structure to their striated muscle counterparts, described above and illustrated in Figures 4.4 and 4.5.

The structure of the underlying actin helix is virtually identical in both types of adductor muscle. An early X-ray diffraction study of molluscan muscles indicated that the structure of F-actin in the smooth adductor of *Pecten chlamys* was similar to that found in *Mytilus edulis* ABRM (Lowy and Vibert 1967), indicating a long-pitch crossover repeat of the order of 36–37 nm, as found in most muscles. Because the ABRM is often considered an experimental analog of the scallop smooth muscle, it is of interest to note that low-angle X-ray diffraction patterns of living ABRM muscle clearly show an intensity change on one of the actin layer lines upon activation of the muscle (Vibert et al. 1972). This is consistent with the movement of tropomyosin deeper into the actin groove upon activation of the muscle, and is suggestive of the presence of thin filament regulation in addition to myosin-linked control. Alternatively, it is also possible that tropomyosin movement occurs here in response to actin attachment by myosin crossbridges and is passive and inconsequential.

Scallop smooth adductor actin is also a β -isoform, similar to actin isolated from the striated adductor (Chantler 1983). Two isoforms of tropomyosin are found in the smooth adductors from *Patinopecten yessoensis* and *Chlamys nobilis*, both isoforms being different from the isoform of tropomyosin isolated from the striated adductor (Ishimoda-Takagi et al. 1986; Ishimoda-Takagi and Kobayashi 1987): one isoform is unique to the smooth adductor, the other appears to be identical to the tropomyosin isoform found in scallop cardiac muscle. Smooth muscle tropomyosin has also been shown to be an activating factor for actin-myosin interaction in the presence of ATP (Takahashi and Morita 1986). Troponin has been isolated from the smooth adductor muscles of *Chlamys nipponensis akazara* (Ojima and Nishita 1986b) and from the Ezo-giant scallop, *Patinopecten yessoensis* (Nishita et al. 1997). In the latter case, all three subunits were purified separately and shown to be functional, albeit restoring only 3-fold calcium sensitivity at best (Nishita et al. 1997). Nevertheless, these results are convincing and indicate that these proteins are not caldesmon degradation products, as had been suggested (Bennett and Marston 1990). Two isoforms of troponin C are expressed from a single gene in *Patinopecten yessoensis* through alternative splicing (Yuasa and Takagi 2000); both of these isoforms are found within the smooth adductor muscle. However, no troponin subunits were found in association with thin filaments prepared from smooth adductor muscles of the Atlantic scallops (Lehman and Szent-Gyorgyi 1975). Consequently, it remains a mystery as to why the scallop catch adductor muscles from some species possess functional troponins whereas others do not.

A second regulatory system involving the calmodulin binding protein, caldesmon (120–140 kDa molecular weight), is found in vertebrate smooth muscles where it dissociates from thin filaments in a calcium-dependent manner (Marston and Smith 1985). In the absence of calcium but the presence of tropomyosin, caldesmon binds to thin filaments and inhibits actomyosin interaction; this inhibition is relieved when calcium-calmodulin binds to caldesmon bringing about dissociation of the calcium-calmodulin-caldesmon complex from the thin filament. Furthermore, when caldesmon is phosphorylated by protein kinase C, it is unable to bind to the thin filament and consequently cannot inhibit the binding of myosin to actin (Yamakita et al. 1992). Caldesmon-like proteins of lower molecular mass (100–110 kDa) have been described in, and isolated from, the catch muscles of several molluscs (Bartegi et al. 1990; Bennett and Marston 1990), including scallops (Bartegi et al. 1990; Malnasi-Csizmadia et al. 1994) and, *in situ*, show a similar localisation to that found in vertebrates. Because a role for caldesmon in the maintenance of the latch state of vertebrate smooth muscle has been proposed (Marston 1989), the possibility that it may also be involved in maintaining the molluscan catch state is attractive (Bennett and Marston 1990). However, while some workers claim that caldesmon is only present in the smooth adductor muscle (Malnasi-Csizmadia et al. 1994), others claim that it shows the same abundance in striated adductor muscles (Bartegi et al. 1990). It has also been suggested that these invertebrate caldesmons are actually catchin molecules (Yamada et al. 2000), a newly reported protein found in smooth adductor muscles (see below). Until these issues are resolved, the role of scallop adductor muscle caldesmons will remain uncertain.

4.3.3 The Structure of Paramyosin-rich Thick Filaments

Paramyosin molecules are long rod-like coiled-coils (Cohen and Holmes 1963; Lowey et al. 1963; Kendrick-Jones et al. 1969) with a 124 nm contour length (Panté 1994); single paramyosin chains have a molecular mass of ~104 kDa (e.g., from *Chlamys nobilis*) (Matsuno et al. 1996); pairs of chains combine in parallel to form functional paramyosin molecules. Paramyosin is found within the core of molluscan thick filaments, exemplified by scallop smooth adductor muscles, hence their categorisation as “paramyosin smooth muscles” (Chantler 1983).

Paramyosin-rich thick filaments are large yet variable in size, >100 µm in length and can be more than 100 nm in diameter (Morrison and Odense 1974; Nunzi and Franzini-Armstrong 1981; Elliott and Bennett 1982); paramyosin typically makes up more than 80% of the thick filament mass (Millman 1967; Szent-Gyorgyi et al. 1971; Elliott 1974; Levine et al. 1976). *Pecten* smooth muscle thick filaments are bipolar in construction, similar to striated adductor thick filaments, but distinguished from them by their much greater size and by the arrangement of myosin with respect to paramyosin: in smooth muscle thick filaments a thin layer of myosin is weakly attached to the surface of the dense paramyosin core, surrounding it completely (Szent-Gyorgyi et al. 1971; Nonomura 1974; Cohen 1982). Comparatively little work has been done on structural aspects of smooth adductor muscles from scallop thick filaments. Although some differences between species have been reported (e.g., Matsuno et al. 1996), it is likely that similarities in the construction of all paramyosin-rich thick filaments transcend species boundaries (Cohen et al. 1971b; Elliott and Bennett 1982). Consequently, much of the information presented here was gained from studies of thick filaments from other molluscan muscles, especially the anterior byssus retractor muscle (ABRM) of *Mytilus edulis*.

Considerable effort has been expended in attempts to determine the structure of the paramyosin core (see Cohen and Szent-Gyorgyi 1971; Elliott and Bennett 1982; Chantler 1983; Bennett and Elliott 1989). Paramyosin cores, from which myosin has been removed, show a characteristic “checkerboard” appearance when seen by negative staining techniques in the electron microscope (Fig. 4.8e) (Hall et al. 1945; Cohen et al. 1971b; Elliott 1979; Matsuno et al. 1996). A unit cell of this array is seen in Figure 4.8g and is identical to the two-dimensional net deduced early-on from low angle X-ray diffraction patterns of molluscan smooth muscles (Bear 1944; Bear and Selby 1956) subsequently known as the “Bear-Selby net”. Measurements of this net indicated a nodal repeat of 72.5 nm in one dimension (the vertical direction in Figure 4.8g) and a more variable distance between nodes at the same level in the second dimension (the horizontal direction in Figure 4.8g). This latter variability was shown to be mainly due to differences in the degree of hydration between samples used in different studies and, under carefully controlled conditions, this internodal distance was shown to be in the range 25–34 nm (Bennett and Elliott 1981).

Figure 4.8. A). Bipolar paramyosin filament. Paramyosin from the white adductor muscle of the clam, *Mercenaria mercenaria*, precipitated from 50 mM Tris, pH 8.0, 1.0 M urea with 50 mM BaCl_2 . The fine striations within the light bands show that the polarity of the arrays is opposite in the two halves of the filament. The band pattern is nonpolar (dihedral) at the centre. B). Paramyosin filament showing a simple polar array from the translucent adductor of *Mercenaria mercenaria* precipitated from 50 mM Tris, pH 8.0, with 50 mM MgCl_2 . C). Paramyosin filament showing a transitional form from the smooth adductor muscle of the scallop, *Argopecten irradians*, precipitated with 50 mM BaCl_2 from 50 mM Tris, pH 8.0, 50 mM KSCN. The subfilament in the center is staggered by 2/5 of a period. This translation generates the net pattern. D). Paramyosin filament showing the synthetic net pattern from the smooth adductor of the scallop, *Placopecten magellanicus*, precipitated with 50 mM BaCl_2 from 50 mM Tris, pH 8.0, 0.1 M KSCN. E). Molluscan thick filament from which myosin has been removed. Paramyosin core from the white adductor of *Mercenaria mercenaria*. F). Two dimensional representation of the molecular packing of paramyosin molecules in the basic polar array. G). Unit cell of the paramyosin net pattern. Figures reproduced, with permission of the publisher, from Cohen and Szent-Gyorgyi (1971).

Paramyosin paracrystals can be obtained through precipitation by divalent cations in the presence of small quantities of chaotropic reagents (Fig. 4.8) (Kendrick-Jones et al. 1969; Cohen et al. 1971b; Cohen and Szent-Gyorgyi 1971). A variety of patterns were obtained when samples were negatively stained and viewed by electron microscopy, including the checkerboard array (Fig. 4.8d). Other arrangements included those with a banding pattern that lacked distinct nodes (Fig. 4.8a, b). These latter patterns could be arranged as non-polar (dihedral) structures (Fig. 4.8a) or as polar assemblies (Fig. 4.8b) (Kendrick-Jones et al. 1969), the polarity being seen by inspection of the minor striations within the main light band. The simplest interpretation of such a banding pattern is that paramyosin molecules do not bond end-to-end but engender gaps (where stain has penetrated) and overlaps (where stain is largely excluded) (Kendrick-Jones et al. 1969; Cohen and Szent-Gyorgyi 1971). Hydrodynamic and light-scattering data indicated that paramyosin molecules were about 135 nm long, as measured within the paracrystalline structure (Lowey et al. 1963). Thus, paramyosin was longer than a single banding repeat (72.5 nm) but shorter than the distance between alternate bands (2×72.5 nm). Hence, its dimensions were consistent with the gap-overlap model, adjacent molecules being staggered by 72.5 nm, the simplest arrangement being seen in Figure 4.8f. This interpretation of the regular paracrystalline banding pattern made it possible to determine the exact length of paramyosin with great precision, a value of 127.5 nm being ascertained (Kendrick-Jones et al. 1969).

Cohen et al. (1971b) suggested that the Bear-Selby net pattern (e.g., Fig. 4.8d, e) could be generated from the polar banding pattern (e.g., Fig. 4.8b) by unrestricted growth in the axial dimension yet restricted growth perpendicular to that axis, the nodal repeat shearing by $2/5 \times 72.5$ nm after only a few intermolecular spacings. An intermediate paracrystalline form that shows one such shear imposed on a polar banding pattern is seen in Figure 4.8c. Removal of surface myosin from thick filaments to yield paramyosin cores also yielded a variety of patterns including banding patterns as well as the Bear-Selby net (Nonomura 1974). That such patterns were manifestations of an underlying crystalline core was shown directly by tilting filament-bearing grids on a goniometer stage so as to view individual filaments after a rotation about their axis (Dover and Elliott 1979; Elliott 1979) or by performing a tilt series using embedded thick filaments cut in transverse section (Bennett and Elliott 1981).

The core of paramyosin-rich molluscan thick filaments is currently viewed as a layered, quasi-crystalline structure. In three dimensions the structure can be envisioned as being composed of two Bear-Selby planar arrays placed in nearly perpendicular apposition to each other (Elliott and Bennett 1984). In any one plane, adjacent paramyosin molecules are staggered by 72.5 nm. The array is not propagated throughout the filament but is sheared periodically in the direction of the filament axis by $2/5 \times 72.5 = 29.0$ nm. There appears to be between 4 and 10 parallel molecular arrays between shear lines, the exact number being species dependent (Elliott and Bennett 1984; Matsuno et al. 1996) and is variable in any one thick filament giving rise to the paracrystalline (as opposed to crystalline) nature of the core. The underlying reasons for the orderly shearing pattern are unknown. The paramyosin core must also be bipolar so as to maintain appropriate bonding with the bipolar arrangement on the surface. This bipolar

arrangement has now been observed directly (Panté 1994), paramyosin assembling such that its amino terminal end points towards the midpoint of the filament (Fig. 4.9) (Weisel 1975; Panté 1994).

The arrangement of the surface layer of myosin which surrounds the paramyosin core is still open to question but is likely to be a monomolecular layer with from one to three myosin molecules associated with each node of the Bear-Selby net (Elliott 1974; Cohen 1982; Panté 1994). Based on sequence analyses of myosin and paramyosin from the nematode, *Caenorhabditis elegans*, a number of optimal charge pairings have been conjectured (Kagawa et al. 1989). Taking into account the known orientations of paramyosin and myosin within the bipolar filament, Panté (1994) has proposed a model (Fig. 4.9), based on an earlier version (Cohen 1982), in which myosin is arranged in an antiparallel manner to paramyosin with a stagger between their respective amino acid sequences of 196 residues – equivalent to 29 nm, a spacing which corresponds to the axial spacing of adjacent Bear-Selby nodes. Vital to this is an assembly competence domain, comprising a 29 amino acid residue region of unique charge profile, that is present at the carboxyl-termini of both molecules (Cohen and Parry 1998). Several models are possible and the one depicted in Figure 4.9c should not be thought of as final; the number of myosin molecules per node and the number of paramyosin molecules within each shear zone are still not known. However, this particular model (Panté 1994) does provide a clear insight into how myosin and paramyosin could be aligned, even to the extent of proposing a function for the ‘skip’ residues – single amino acid interruptions within the coiled-coil heptad repeat – which are also aligned within the two polypeptide sequences, suggesting they provide a form of “ball and socket” stabilisation.

It remains unclear that the proposed structure (Fig. 4.9) would provide for nodal radial symmetry (hence a radial distribution of myosin) around the filament. Such an arrangement is necessary because thin filaments have been observed to be distributed radially around these thick filaments (Lowy and Hanson 1962; Elliott 1964; Elliott and Bennett 1982; Lowy and Poulsen 1982) and radially arranged crossbridges can be visualised under rigor conditions (Sobieszek 1973; Bennett and Elliott 1981). It is also possible that myosin could be organised in a helical manner around the filament, as has been observed in some paramyosin-containing muscles where the molar ratio of paramyosin to myosin is close to unity (Castellani et al. 1983). This would provide a way for myosin to get around the “corners” and attain a radial distribution, the myosin coiled-coil possibly being placed at some, as yet unspecified, angle to the paramyosin coiled-coil. Note that stoichiometries obtained for the relative abundance of myosin and paramyosin in molluscan smooth muscle thick filaments (Szent-Gyorgyi et al. 1971; Elliott 1974; Levine et al. 1976) are not so precise as to place the concept of a single myosin surface layer beyond question. The essence of this concept is that from one to three myosin molecules, present within a surface area of $43,500 \text{ \AA}^2$, would exhibit properties such that myosin-paramyosin interactions predominate (Cohen 1982); surface myosins present on the thick filaments of non-catch muscles, where myosin-myosin interactions predominate, are squeezed into a surface area of some $15,000 \text{ \AA}^2$ (Cohen 1982). Small changes in the measurement of molecular stoichiometries, filament dimensions or molecular packing,

Figure 4.9. Possible molecular arrangement of myosin and paramyosin molecules in the native thick filament of molluscan smooth muscle. a). Antiparallel, lateral arrangement of myosin and paramyosin molecules for a stagger ($s = -196$ residues) in which the carboxyl terminal end of paramyosin is shifted away from the amino terminal end of the myosin rod by ~ 29 nm. Short vertical bars indicate skip residues of which the positions of two on either molecule (arrows) coincide. b). Schematic arrangement of paramyosin subfilaments illustrating relationship to 29 nm nodal gap stagger. In the lower subfilament, myosin (as in a)) is superposed. c). Schematic model to illustrate a possible arrangement of myosin within the thick filament relative to the Bear-Selby net. The latter is generated by shifting paramyosin subfilaments by 29 nm. Myosin heads are shown to coincide with nodal gaps, but other arrangements are possible. For simplification, only one paramyosin molecule is drawn per node and only four myosins are drawn on either side of the thick filament. Adapted from Panté (1994) and reproduced with permission of the publisher.

could have profound effects on the concept of whether myosin-paramyosin or myosin-myosin interactions predominate.

Myosin isolated from *Patinopecten yessoensis* smooth adductor possessing an isoform of the regulatory light chain, R-LCa, undergoes phosphorylation at Ser-11 of R-LCa (Sohma et al. 1985). This was shown using either gizzard myosin light chain kinase (MLCK) (Sohma et al. 1985) or an endogenous kinase purified from the smooth adductor (Sohma and Morita 1986; Sohma and Morita 1987; Sohma et al. 1988a). A calcium-dependent calcineurin-like phosphatase has been shown to dephosphorylate phosphorylated R-LCa (Inoue et al. 1990); whether this protein is related to the calcineurin-like phosphatase implicated in catch contraction (Castellani and Cohen 1992) is not yet known. These data are suggestive of a form of regulation more akin to vertebrate smooth muscle than to the regulation of scallop striated adductor myosin. Sequence analysis of the larger smooth muscle R-LC isoform (smoA) from *Placopecten* confirmed (Perreault-Micale et al. 1996a) the presence of a phosphorylation consensus sequence (Kemp and Pearson 1985); smoA could also be phosphorylated by MLCK (Perreault-Micale et al. 1996a). However, hybrid studies demonstrated that the ATPase obtained was characteristic of the parent myosin heavy chain (MHC) and the ATPase

rates were not altered irrespective of R-LC phosphorylation (Perreault-Micale et al. 1996a). Thus, whether or not the specific phosphorylation of R-LCa or smoA portends a role in the regulation of catch contraction remains an open question.

Myosin from the ABRM of *Mytilus edulis* has been shown to be a substrate for heavy-chain phosphorylation by an endogenous heavy-chain kinase or by a heavy-chain kinase isolated from the slime mold, *Dictyostelium* (Castellani and Cohen 1987a; Castellani and Cohen 1987b). Heavy chain phosphorylation occurs at a serine residue within the tail-piece sequence, an extended region not found in striated adductor myosin (Castellani et al. 1988). A second phosphorylation site noted by these authors is actually found within the N-terminal sequence of catchin (Yamada et al. 2000) (see below). It was shown, *in vitro*, that this phosphorylation enhances the ability of the myosin molecule to fold at low ionic strength (Castellani and Cohen 1987b) suggesting that events in the neck region of the myosin molecule could be modulated by phosphorylation at the tip of the tail. Myosin heavy chain phosphorylation has also been demonstrated to occur in smooth adductor muscles of *Patinopecten yessoensis* using an endogenous kinase previously characterised as phosphorylating R-LCa (Sohma et al. 1988b).

The most important new thick filament protein to emerge recently, unrelated to myosin or paramyosin, is twitchin. As noted above, mini-titins, otherwise known as twitchins, are giant kinase molecules found in both scallop striated and smooth adductor muscles where they are located within the A-band and at the A-I junction (Vibert et al. 1993). Recently, Marion Siegman and collaborators (Siegman et al. 1997; Siegman et al. 1998) set out to find which proteins became phosphorylated when an ABRM (*Mytilus edulis*) muscle was released from the catch state, either by application of serotonin to the intact muscle or by the addition of cAMP to permeabilised muscles. Surprisingly, a 600 kDa protein exhibited the greatest increase in phosphorylation (Siegman et al. 1997) and was shown to be twitchin through a cDNA cloning strategy that used N-terminal amino acid sequence data to derive PCR primers (Siegman et al. 1998). The molar ratio of twitchin to myosin in these muscles was shown to be 1:15 and the level of cAMP-induced phosphorylation was somewhat greater than 0.5 mole/mole.

Catchin is the name given to a pair of new players on the scene – novel heat-stable, phosphorylated rod-shaped molecules, 112 kDa and 120 kDa in size, characterised from the catch adductor muscles of the scallop, *Argopecten irradians* and the mussel, *Mytilus galloprovincialis* (Yamada et al. 1997; Yamada et al. 2000). Often noted as an abundant contaminant of paramyosin preparations (Panté 1994), catchin had previously been identified as a proteolytic cleavage product of myosin (Castellani et al. 1988) through partial sequencing. Determination of the complete sequence (Yamada et al. 2000) revealed that catchin is an alternatively spliced product of the MHC gene with a unique non-helical N-terminal sequence comprising 156 amino acid residues, including a phosphorylatable serine; the remaining 830 C-terminal residues are identical to the MHC coiled-coil rod sequence distal to the S-2 junction and include the non-helical tail-piece. The unique N-terminus of catchin is encoded within the large intron following exon-18 of the smooth adductor MHC sequence (Nyitray et al. 1994). The contour length of catchin, 125 nm, is almost identical to that of paramyosin (Yamada et al. 1997; Yamada et al. 2000). While the presence of catchin (Yamada et al. 2000) and twitchin (Siegman et al.

1998) clearly have implications for the catch mechanism (see below under Catch Mechanism), nothing is known at present as to how these proteins are incorporated into, or interact with, the paramyosin smooth thick filament structure.

4.4 MYOSIN

Scallop adductor myosin is a regulatory myosin, possessing the necessary machinery within its own structure to control its interaction with actin. Similar to other conventional myosins it is composed of two heads (each ~16.5 nm in length, ~6.5 nm wide and ~4 nm thick) and a long tail (~150 nm in length) (Fig. 4.10). The N-terminal halves of each of the two myosin heavy chains (MHCs) (~200 kDa each) separately fold to form the heads of the molecule while the α -helical C-terminal halves wrap around each other to form the coiled-coil tail. Within each head the first ~780 residues of the MHC form the motor domain featuring the actin-binding and ATPase sites; each MHC then extends as a long α -helix stabilised by two light chains (LCs) (~20 kDa each) forming a distinct regulatory domain (RD) or lever arm. The essential light chain (E-LC) abuts the motor domain while the regulatory light chain (R-LC), furthest from the head, abuts the E-LC. Unlike their vertebrate counterparts, scallop striated and smooth muscle MHCs are expressed from a single gene as alternatively-spliced products (Nyitray et al. 1994). This gene, in *Argopecten irradians*, is 24 kilobases in size and is composed of 27 exons of which at least four are present in tandem pairs and are alternatively spliced in the striated and catch adductors (Nyitray et al. 1994). A minor catch isoform expressing a fifth alternatively-spliced exon (exon 13), that was noted in *Argopecten irradians* (Nyitray et al. 1994), was found to be the predominant isoform in *Placopecten magellanicus* catch myosin (Perreault-Micale et al. 1996b). Whereas the catch muscle MHC is also found in scallop foot, mantle, gonad and heart muscles, the striated muscle isoform appears to be expressed exclusively in the striated adductor muscle.

Complete primary amino acid sequences have been obtained for the MHCs (Nyitray et al. 1991; Perreault-Micale et al. 1996b; Janes et al. 2000), R-LCs (Kendrick-Jones and Jakes 1977; Collins et al. 1986; Goodwin et al. 1987; Perreault-Micale et al. 1996a; Janes et al. 2000) and E-LCs (Collins et al. 1986; Goodwin et al. 1987; Perreault-Micale et al. 1996a; Janes et al. 2000) of myosins from the striated adductor muscles of the Atlantic scallops *Argopecten irradians* (Collins et al. 1986; Goodwin et al. 1987; Nyitray et al. 1991), *Placopecten magellanicus* (Perreault-Micale et al. 1996a; Perreault-Micale et al. 1996b) and *Pecten maximus* (Kendrick-Jones and Jakes 1977; Janes et al. 2000). These are displayed and aligned in Figs. 4.11 and 4.12, where they are compared with the primary sequences of the catch adductor MHCs from *Argopecten irradians* (Nyitray et al. 1994) and *Placopecten magellanicus* (Perreault-Micale et al. 1996b).

Pecten maximus MHC cDNA was found to contain an open reading frame of 5,820 nucleotides encoding 1,940 amino acid residues as compared with 1,938, 1,941 and 1,935 amino acids which make up the MHCs of *Argopecten irradians*, *Placopecten magellanicus* and *Loligo pealei* (squid) striated muscle myosins, respectively (Fig. 4.11). Analysis of the *Argopecten* MHC sequence defined a number of residues required for regulation (Nyitray et al. 1991); these residues are conserved in all the regulatory MHC

Figure 4.10. Schematic diagram of the myosin molecule (not drawn to scale) showing the organisation of the three pairs of polypeptide chains (myosin heavy chain; regulatory light chain (R-LC); essential light chain (E-LC)) and major proteolytic fragments (single headed subfragment-1 (S-1); double-headed heavy meromyosin (HMM); coiled-coil tail proximal to the heads (S-2); coiled-coil tail distal from the heads (LMM)). Modified from Rayment and Holden 1994 and reproduced with permission from the publisher. Inset: Rotary-shadowed electron microscopic image of scallop striated adductor myosin; Chantler and Kensler, unpublished.

sequences (Fig. 4.11). The three scallop MHC sequences are closely homologous to each other (Janes et al. 2000), the *Pecten* sequence exhibiting 97.5% and 95.6% identity to the *Argopecten* and *Placopecten* MHC sequences, respectively; by contrast, only 73.6% identity was found relative to a molluscan MHC sequence from squid (*Loligo pealei*) siphon retractor muscle (Matulef et al. 1998). *Placopecten* striated adductor myosin displays a higher actin-activated MgATPase rate than either *Argopecten* or *Pecten* myosins (Chantler and Szent-Gyorgyi 1980; Chalovich et al. 1984; Perreault-Micale et al. 1996b; Patel et al. 2000). Key sequence differences within a surface loop (Loop 1) (Spudich 1994) structure close to the nucleotide binding pocket, encoded by exon 5, are thought to account for these different turnover rates (Perreault-Micale et al. 1996b; Kurzawa-Goertz et al. 1998). Differences found within the catch muscle isoforms arise from the five alternatively-spliced exons. Three of these regions are found within the myosin head and encode the phosphate binding loop and Loop 1 (exon 5), part of the ATP binding cleft (exon 6) and a linking region between the ATP site and the actin-binding site (exon 13). The other two regions are within the tail and encode the S2 hinge region (exon 20) and lead to an additional ten amino acids within the catch isoform at the C-terminus of the non-helical tail-piece (exon 26) (Fig. 4.11) (Nyitrai et al. 1994; Perreault-Micale et al. 1996b). The actin-activated MgATPase activity of myosin and myosin head (S-1) fragments isolated from the smooth adductor are two to three times lower than those measured for the striated adductor (Perreault-Micale et al. 1996a; Perreault-Micale et al.

1996b); these differing rates arise from differing values of $V_{\max}$ but not K_M (Perreault-Micale et al. 1996b) and are attributed to variations in the Loop 1 sequence because alternatively spliced sequences of exons 6 and 13 are identical within analogous muscles of the two species. No alternative splicing of Loop 2 has so far been detected in molluscan myosins. It is important to note that these reported sequence differences, while relevant to catch, cannot be the sole determinants of the catch mechanism because the smooth muscle isoform possessing all alternatively spliced regions was also detected in scallop mantle and heart muscle (Nyitray et al. 1994).

The deduced sequence of *Pecten* R-LC has 156 amino acids, exhibiting 97.4% identity to that found in *Argopecten* R-LC (Goodwin et al. 1987) and 90.4% identity to *Placopecten* R-LC (Perreault-Micale et al. 1996a) (Fig. 4.12a). Glycine-117, a residue previously shown to be critical for regulation (Jancso and Szent-Gyorgyi 1994), is conserved in all molluscan R-LCs so far sequenced: this residue is responsible for maintaining hydrogen bonding to the adjacent E-LC and is critical to the regulatory mechanism (see below). The deduced amino acid sequence of *Pecten* E-LC also has 156 amino acids, exhibiting 99.4% identity to the *Argopecten* E-LC (Goodwin et al. 1987) and 94.2% identity to *Placopecten* E-LC (Perreault-Micale et al. 1996a) (Fig. 4.12b). In addition, R-LC (Maita et al. 1984; Miyanishi et al. 1985) and E-LC (Maita et al. 1987) sequences have been determined for myosins from the striated adductor muscles of the Japanese scallops, *Patinopecten yessoensis* (Maita et al. 1984; Miyanishi et al. 1985; Maita et al. 1987) and *Chlamys nipponensis akazara* (Maita et al. 1984).

The sequence of the E-LC found in the smooth adductor muscle of *Placopecten magellanicus* is identical to its counterpart found in the striated adductor (Perreault-Micale et al. 1996a). However, two distinctive amino acid sequences have been determined for R-LCs isolated from the smooth adductor muscles of each of *Patinopecten yessoensis* (Miyanishi et al. 1985) and *Placopecten magellanicus* (Perreault-Micale et al. 1996a) which differ from their striated counterparts (Fig. 4.12a). Because the catch adductor muscle closely approximates the striated adductor muscle along its innermost surface (see Fig. 4.1), it is not too surprising that there is a gradual transition in fibre type from striated to smooth, moving from the inside surface to the outside of the catch adductor (Ruegg 1961). Consistent with this, there is a gradual transition in myosin type across the smooth adductor (Kondo and Morita 1981; Morita and Kondo 1982): the R-LC associated with the catch portion (R-LCa) of *Patinopecten* is found only around the outer perimeter of the muscle (Miyanishi et al. 1985); the larger of the two R-LCs (smoA) found in *Placopecten* is found only within the catch portion of the muscle whereas the other smooth muscle R-LC isoform (smoB) is present both in the intermediate and catch portion of the smooth muscle (Perreault-Micale et al. 1996a). Most amino acid differences occur within the N-terminal 52 residues; analysis of genomic DNA by Southern blotting and PCR suggests that all three isoforms (striated, smooth A and B) are generated by alternative splicing of a single gene (Perreault-Micale et al. 1996a).

Figure 4.11. Comparison of deduced sequences for myosin heavy chains from the striated (line 1: *Pecten maximus*; line 2: *Argopecten irradians*; line 3: *Placopecten magellanicus*) and smooth (line 4: *Argopecten irradians*; line 5: *Placopecten magellanicus*) scallop adductor muscles as well as from squid (*Loligo pealei*) syphon retractor muscle (line 6). Periods (.) indicate sequence as for *Pecten* striated muscle myosin heavy chain. Residues deduced to be involved in regulation (Nyitray et al. 1991; Matulef et al. 1998) are highlighted (blue) by asterisks. Attention is drawn to key features of the heavy chain sequence including SH3, the P-loop, the 25/50 kDa loop-1 junction, the 50/20 kDa loop-2 junction, Switch I and Switch II subdomains, the relay, converter and the fast-reacting thiols, SH1 and SH2, together with the non-helical tailpiece found in smooth myosin isoforms (all in green); as well as the malleable helix in-between SH1 and SH2 that is capable of melting upon nucleotide binding (bright green), the E-LC and R-LC binding regions (turquoise), residues involved in ATP binding (red), actin binding regions (violet), the “terminal” proline residue which marks the head/tail boundary (green and underlined), the four skip residues within the rod portion of the tail (pink and underlined). Attributions are: *Pecten maximus* striated myosin HC (Janes et al. 2000); *Argopecten irradians* striated myosin HC (Nyitray et al. 1991); *Argopecten irradians* smooth myosin HC (Nyitray et al. 1994); *Placopecten magellanicus* striated and smooth myosin HC isoforms (Perreault-Micale et al. 1996b); *Loligo pealei* syphon retractor muscle myosin HC (Matulef et al. 1998). Figure adapted and expanded from Janes et al. (2000). Single letter codes for the amino-acids are: D, aspartate; E, glutamate; N, asparagine; Q, glutamine; G, glycine; A, alanine; V, valine; L, leucine; I, isoleucine; S, serine; T, threonine; F, phenylalanine; W, tyrosine; Y, tryptophan; M, methionine; P, proline; K, lysine; R, arginine.

Figure 4.12. Comparison of deduced sequences for the main isoforms of a) regulatory light chain (R-LC) and b) essential light chain (E-LC) from the striated muscles of each of three species of scallop: *Pecten maximus* (line 1); *Argopecten irradians* (line 2) and *Placopecten magellanicus* (line 3) and from the SmoA and Smo B isoforms of *Placopecten magellanicus* (R-LC, lines 4. & 5). E-LC isoforms are identical in striated and smooth muscles. The non-specific divalent cation binding site on the R-LC (red) and the Ca²⁺-specific site on the E-LC (blue) are indicated; the R-LC glycine residue critical for regulation (Gly117) is also highlighted (blue). Single letter codes for the amino-acids are as defined in the legend to Figure 4.11. Periods (.) indicate sequence as for *Pecten* striated. Asterisks indicate extra residues present in the smooth R-LC isoforms but missing in their striated counterparts. Sequences determined by Janes et al. 2000 (*Pecten* striated R-LC and E-LC); Goodwin et al. 1987 (*Argopecten* striated R-LC and E-LC); Perreault-Micale et al. 1996a (*Placopecten* striated and smooth R-LC and E-LC). The N-terminus of each light-chain is most likely blocked by an acetyl group, as has been shown for *Pecten* R-LC (Kendrick-Jones and Jakes 1977). Figure adapted and expanded from Janes et al. 2000.

The determination of the structure of the isolated myosin head was a seminal *fin-de-siècle* achievement. First accomplished for chicken skeletal myosin (Rayment et al. 1993a), the effort has been repeated on myosin heads from *Dictyostelium* myosin II (Fisher et al. 1995), chicken smooth muscle myosin (Dominguez et al. 1998) and scallop (*Argopecten irradians*) striated adductor muscle myosin (Houdusse et al. 1999), each in the presence of various nucleotide analogs. The structure of the scallop myosin head, with ADP present at the active site, is seen in Figure 4.13 (Houdusse et al. 1999). Key landmarks (note locations shown within the sequence in Figure 4.11) on each globular head include the nucleotide binding pocket, the entrance to which is guarded by the 25/50 kDa loop (Loop 1); the actin binding site, which is closely associated with the 50/20 kDa loop (Loop 2); the SH3 domain, which has been suggested to limit the potential swing of the lever arm (Dominguez et al. 1998); the converter domain, important for communication between the motor domain and the lever arm (Dominguez et al. 1998); the regulatory domain (RD), where the long α -helix extending from either head is grasped by the two light chains, the E-LC being closest to the head. Both loop structures are variable in sequence and must be flexible because they cannot be visualised in the crystal structures; their function appears to be to control actin affinity (Loop 2), ATPase (Loops 1 and 2) and ADP release (Loop 1) rates (Spudich 1994; Kurzawa-Goertz et al. 1998; Murphy and Spudich 2000).

An understanding of the mechanism of myosin action has emerged from the crystallographic structures of myosin heads in the presence and absence of nucleotides. The conformation of the scallop myosin head, determined in the presence of MgADP, is unique among current structures: it has been referred to as a third state of myosin (state III), and has been compared critically to the other two key structural states (Houdusse et al. 1999; Houdusse et al. 2000). State I was first seen in chicken skeletal myosin in the absence of nucleotide (but with a sulphate ion within the phosphate binding pocket) (Rayment et al. 1993a) and more recently in scallop myosin in the absence of nucleotide (Houdusse et al. 2000); state II has been observed in chicken smooth muscle myosin in the presence of MgADP·AlF₄⁻ (Dominguez et al. 1998) and in scallop myosin in the presence of MgADP·VO₄ (Houdusse et al. 2000). Similarities, as well as profound differences, between these three structures have been noted (Fig. 4.14). All three show conformationally invariant domains (the N-terminal domain, the upper 50 kDa domain; the lower 50 kDa domain and the converter domain) which are displaced relative to one another in each of the three states (Houdusse et al. 1999). To date, such a comparison within a single species is only possible for myosin from the scallop striated adductor muscle (Houdusse et al. 2000). In state III, the “jaws” of the 50 kDa domain are open (Houdusse et al. 1999), similar to the nucleotide-free structure (Rayment et al. 1993a; Houdusse et al. 2000); these differ from the partially closed form of the smooth myosin structure which is thought to represent the transition state complex (Fisher et al. 1995; Dominguez et al. 1998) (Fig. 4.14). The relative dispositions of the invariant domains with respect to each other appear to be determined by the presence of three flexible joints: switch II, the relay and the SH-1 helix (Fig. 4.14). Of these, small conformational changes in switch II, consequential to sensing the changing chemistry at the active site, lead to altered associations between the relay and the SH-1 helix (see Fig. 4.14).

Figure 4.13. Structure of a scallop myosin head in the presence of MgADP. It is drawn using RasMol (version 2.4), coordinates being downloaded from the Protein Data Bank, Research Collaboratory for Structural Bioinformatics, Rutgers University (accession code 1b7t) (Houdusse et al. 1999). Illustrations are rendered as wire-frame structures on which the α -carbon backbone has been highlighted. Heavy-chain residues highlighted comprise: the converter region (residues Gly-695 - Phe-762; red); those amino acids which outline the 25/50 kDa cleft and the nucleotide binding cleft (residues Gln-170 - Lys-256; violet); surface loops (residues Lys-139 - Thr-146 and Asn-162 - Asn-169; orange), which have been shown to contact the E-LC in the chicken motor domain MgADP.AIF₄/E-LC structure (Dominguez et al. 1998); a region within the N-terminal SH3 domain (residues Ala-45 - Lys-60; light blue) which has been shown to be in close contact with the E-LC in the scallop MgADP S-1 structure (Houdusse et al. 1999). The R-LC is shaded red. The E-LC is shaded yellow. Residues shaded green within the E-LC structure indicate amino acids inferred to be involved in TFP binding (Patel et al. 2000). All other regions of the heavy-chain are shaded deep blue. Figure adapted from Patel et al. (2000) and reproduced with permission of the publisher.

Switch II also influences communication between the active site and the actin-binding surface and is critical to the putative release of inorganic phosphate through a separate exit at the base of the nucleotide cleft – known as the “back door” (Yount et al. 1995). The converter, which arises directly from the C-terminal end of the SH-1 helix, shows the greatest positional change in the three states (Houdusse et al. 2000); the lever arm is contiguous with the converter. Consequently, a small conformational change in switch II leads to altered inter-domain relationships, especially the relative orientations of the lower 50 kDa and converter domains, the lever arm effectively magnifying these changes by “wagging its tail”.

The structure of the scallop striated adductor muscle myosin RD (+Ca²⁺) has also been obtained, separately, and at high resolution (Xie et al. 1994; Houdusse et al. 1996) (Fig. 4.15). In regulatory myosins, activity of the motor domain is triggered directly or indirectly by the primary Ca²⁺ signal through a switch located within the RD. In the form of myosin regulation epitomised by vertebrate smooth muscle and non-muscle cells, Ca²⁺ triggers activation of myosin light chain kinase (MLCK) which catalyses the phosphorylation of a serine residue within each R-LC (Pfitzer 2001). By contrast, myosin-linked regulation is found in its simplest form in the striated adductor muscles of molluscs where the triggering ion binds directly and specifically to the first helix-loop-helix motif of the E-LC (Xie et al. 1994). Although the light chains belong to a family of proteins characterised by the possession of four potential EF hand motifs (Collins et al. 1986), X-ray structural analysis revealed that the calcium-specific binding site on scallop myosin E-LC does not conform to a classic EF-hand, as originally described for parvalbumin (Kretsinger and Nockolds 1973); instead, all seven liganding groups are provided by oxygen donors, including one water molecule and three backbone carbonyls, from within the tight horseshoe of a 9-residue loop (Houdusse and Cohen 1996). By contrast, the first helix-loop-helix motif of the scallop R-LC is a functional archetypal EF-hand, but can only bind divalent cations non-specifically (Bagshaw and Kendrick-Jones 1979; Bagshaw and Kendrick-Jones 1980). Neither light chain can bind calcium specifically or with high affinity when dissociated from myosin. The RD structure of scallop myosin reveals how the integrity of the E-LC calcium-specific horseshoe loop depends critically on contacts made between the R-LC and the E-LC over a very limited region. Two key hydrogen bonds originate from Gly-117 of the R-LC (Xie et al. 1994; Houdusse and Cohen 1996), a residue shown to be critical for stabilisation of the calcium-specific binding site (Jancso and Szent-Gyorgyi 1994), and make contact with the Phe-20 carbonyl oxygen and Arg-24 amido nitrogen of the E-LC. The side-chain of E-LC Arg-24 also makes two hydrogen bonds with R-LC Asp-118 (Houdusse and Cohen 1996).

The E-LC and R-LC structures are organised as a pair of lobes (Fig. 4.15); each lobe can adopt one of three conformations (Houdusse and Cohen 1995; Houdusse and Cohen 1996). The N-terminal lobe of the R-LC binds Mg²⁺ creating an ‘open’ state, facilitating non-polar interactions with the hydrophobic face of the MHC helix (Houdusse and Cohen 1996) whereas the N-terminal lobe of E-LC, when bound to the triggering Ca²⁺, is in a ‘closed’ form and does not grip the MHC but is stabilised by interactions with the R-LC (Houdusse et al. 1996). These two conformations resemble those seen in calmodulin and troponin C which can form open, or closed, states in the divalent cation bound, or

Figure 4.14. Subdomain arrangement in the three states of scallop myosin heads. All three states have been determined for scallop myosin (Houdusse et al. 2000) and have also been determined, individually, for chicken skeletal myosin heads in the absence of nucleotide (Rayment et al. 1993a) and *Dictyostelium* myosin heads in the presence of ADP·BeF₃ (Fisher et al. 1995) (state I); chicken smooth muscle myosin in the presence of ADP·AlF₄⁻ (Dominguez et al. 1998) and *Dictyostelium* myosin heads in the presence of ADP·VO₄ (Smith and Rayment 1996) (state II). Ribbon diagrams of the three states are shown on the left-hand side together with explanatory diagrams illustrating the relative dispositions of the invariant subdomains together with the flexible “joints” that link them together. Arrows indicate the direction of movement of the lower 50 kDa domain and the converter domain as compared with the state I. See text for details. Adapted from Houdusse et al. (1999) and reproduced here with permission of the publisher.

unbound forms, eliciting a significant change of conformation to create a hydrophobic cleft capable of binding a target α -helical peptide (Ikura et al. 1992; Vassilyev et al. 1998). Additionally, the C-terminal lobes of both the E-LC and R-LC (but not calmodulin or troponin C) display a third 'semi-open' state in which no metal is bound yet the MHC is gripped by the tips of these lobes (Houdusse and Cohen 1995; Houdusse et al. 1996). The same "IQ" motif (residues 788 to 798 of the *Pecten* MHC sequence) is gripped, from opposite sides, by the C-terminal and N-terminal lobes of the E-LC, whereas the C-terminal and N-terminal lobes of the R-LC grip tandem segments of the MHC (residues 814 to 836) (Xie et al. 1994; Houdusse et al. 1996). A $\sim 40^\circ$ bend in the MHC at the location of the E-LC-R-LC interface and an $\sim 80^\circ$ bend in the MHC located between the separate grips of the N and C-terminal lobes of the R-LC have been identified as sites of flexibility (Houdusse et al. 1996; Offer and Knight 1996).

When a regulatory myosin is in the off-state, its intrinsic MgATPase (Wells and Bagshaw 1985), actin-activated MgATPase (Kendrick-Jones et al. 1976; Chantler and Szent-Gyorgyi 1980) and actin-mediated motility (Vale et al. 1984) are inhibited. The relay of conformational changes, which enables ligand binding to the RD to switch on the motor, remains elusive. While the MHC converter region is critically placed, connecting a relatively rigid relay loop within the motor domain to the lever arm (Dominguez et al. 1998; Houdusse et al. 1999), it remains unclear how ligand binding to the LCs brings about conformational changes at the converter/E-LC interface necessary for activation. Trifluoperazine (TFP), a powerful inhibitor of calmodulin action, also binds to the C-terminal lobe of the scallop myosin E-LC and inhibits ATPase turnover (Patel et al. 2000). Regulation is not observed in S-1, the single head cleaved from myosin by proteolysis (Szent-Gyorgyi et al. 1973; Kalabokis and Szent-Gyorgyi 1997). The regulatory system thus transcends a single head and indeed, cooperative interactions between the heads underlie regulation. There is a requirement that both heads must bind Ca^{2+} (Chantler et al. 1981; Walmsley et al. 1990; Kalabokis and Szent-Gyorgyi 1997), in order to activate the molecule. The existence of head-head interactions is also shown by the negatively cooperative binding of R-LCs to R-LC-denuded myosin (Chantler and Szent-Gyorgyi 1980). However, a two-headed structure alone may not be sufficient for regulation since smooth myosin with a very short tail exhibits diminished regulation (Trybus et al. 1997); furthermore, single-headed scallop myosin retains a regulatory capability not seen in S-1 (Stafford et al. 1979), albeit lacking cooperativity (Kalabokis et al. 1996). Collectively, these observations suggest that head-head and head-tail interactions play a crucial role not only in producing cooperativity but also in the regulatory mechanism itself.

Despite the recent advances in myosin structure determination, atomic detail is currently confined to single-heads (Rayment et al. 1993a; Dominguez et al. 1998; Houdusse et al. 1999; Houdusse et al. 2000) or head fragments (Xie et al. 1994; Fisher et al. 1995; Houdusse and Cohen 1996). Two-headed fragments of myosin are too large for NMR structural determination and have not yet yielded diffractable crystals. As an alternative approach, an atomic model of the head-tail junction of scallop striated adductor muscle myosin was published (Offer and Knight 1996) derived by combining the known structure of key fragments through computer modelling. It predicted a number of specific interactions between the heads and between the heads and the tail. The construction of the

Figure 4.15. Structure of the regulatory domain (+Ca²⁺) from scallop striated adductor myosin. This ribbon diagram demonstrates the distinctive interactions of the two lobes of each light chain with the underlying heavy chain (grey). All four subdomains (I through IV) are shown for both the regulatory (R-LC) and essential (E-LC) light chains. While each subdomain is capable of binding calcium in the related molecule, calmodulin (Houdusse and Cohen 1995), only subdomain I can bind divalent cations in the bound light chains; subdomain I of the R-LC possesses a non-specific divalent cation site (bound Mg²⁺ is shown as a red sphere); subdomain I of the E-LC possesses a calcium-specific site (bound Ca²⁺ also shown as red sphere) provided that both light chains remain bound. Note that the two lobes of the R-LC grasp the heavy chain in tandem whereas the two lobes of the E-LC interact with opposite sides of the same region of heavy chain - the E-LC N-terminal lobe making only surface contacts rather than tightly gripping the heavy chain. The long α -helix of the heavy chain shows a $\sim 40^\circ$ bend in the region between the two light chains and an $\sim 80^\circ$ bend in the region gripped by the N-terminal lobe of the RLC. Figure reproduced, with permission of the publisher, from Houdusse and Cohen (1996).

model was guided by an understanding of the side-chain packing in two-chain α -helical coiled-coils (Offer and Sessions 1995) leading to a model in which the two heads lay alongside one another, with their bases in contact but without steric clash (Fig. 4.16a). The principal interactions between the two heads were between the N-terminal lobe of a R-LC of one head and the C-terminal lobe of the R-LC on the other head; there were also head-tail interactions between each R-LC and its partnering MHC in the coiled-coil region (Offer and Knight 1996). Three pairs of residues within the R-LCs on either side of these interfaces (Ala42-Arg126, Glu45-Lys130, Gln46-Glu131) were in close proximity and demonstrated complementary charges suggesting the formation of salt links. The resulting model accounted for some of the conserved sequence features found in regulatory myosins and provided a structural basis for understanding head-head and head-tail interactions in regulated myosins. Functional consequences of this model were tested directly by site-directed mutagenesis: expressed R-LCs in which Arg126, Lys130 and Glu131 were converted to alanine residues, either singly, in pairs or as a triple mutant, then recombined with R-LC denuded scallop myofibrils (Colegrave et al. 2003) were analysed for regulation. If the symmetric model was correct in detail then each of these mutations, singly or in combination, should have disrupted normal regulation. However, it was found that regulation, as measured either through calcium binding, calcium dependent actin-activated MgATPase or actin sliding, was not impaired (Colegrave et al. 2003), suggesting that the symmetric model was inadequate to explain head-head cooperativity (Chantler et al. 1981) and calcium-dependent regulation (Chantler and Szent-Gyorgyi 1980).

An alternative model, derived from vertebrate smooth muscle (which is subject to regulation through R-LC phosphorylation), has also been proposed recently (Wendt et al. 1999; Wendt et al. 2001). It defines an asymmetric structure for the inhibited state, determined by electron microscope imaging of dephosphorylated myosin arrays within 2D lipid monolayers (Wendt et al. 1999; Wendt et al. 2001); the actin binding surface of one head abuts the converter domain of the adjacent head. This model is further supported by both crosslinking (Wu et al. 1999) and kinetic (Nyitai et al. 2002) data. Furthermore, the R-LC residues that were mutated in order to appraise the symmetric model (Colegrave et al. 2003) can be seen to be widely separated in the asymmetric model (Fig. 4.16b), explaining why these mutations had minimal effect on regulation. In this regard, it may be noted that while R-LC dissociation is a random event at temperatures $\sim 20^\circ$ (Chantler 1985) and is fairly fast, the rate being 0.014 s^{-1} (partially limited by the rate of dissociation of Mg^{2+} (0.058 s^{-1}) from the non-specific divalent cation site) (Bennett and Bagshaw 1986b), at temperatures $< 20^\circ\text{C}$ dissociation is biphasic. This indicates that the binding constants for the R-LCs are not equivalent under these conditions (Chantler 1985), results that are consistent with an asymmetric structure. Further work needs to be done in order to verify the details of the asymmetric structure for the off-state of scallop myosin, but the ultimate goal of understanding regulation and cooperativity in the two-headed scallop myosin molecule appears to be attainable.

Views of the asymmetrical model of smooth muscle myosin (Code 1I84, Protein Data Bank, Research Collaboratory for Structural Bioinformatics, Rutgers University) adapted to illustrate the location of the critical residues depicted for scallop myosin. Peptides colour-coded as in a). The residues in the R-LCs that are proposed to contact each other in the Offer & Knight model (a) are indicated; note that these sets of residues, on each of the regulatory light chains, are far apart from each other in this model. Image data derived from Wendt et al. (1999). Image shown copyright © of the Biochemical Society and reproduced here with their permission.

4.5 FUNCTION OF THE STRIATED ADDUCTOR

4.5.1 Mechanics

The cellular organisation of the scallop striated adductor muscle, described earlier, is designed to perform external work during a limited number of contractions rather than to maintain force during a single contraction. This is apparent from the work of Rall (1981), who compared the mechanics and energetics of contraction of the striated adductor muscle of *Placopecten magellanicus* to the more favoured experimental subject for physiology, the semitendinosus muscle of the frog, *Rana pipiens*. Such a conclusion also makes sense from what we know about the action of the striated adductor muscles *in vivo*: swimming by jet propulsion occurs because of the repeated expulsion of water by adduction of the shells, brought about through a series of contractions by the striated adductor muscle (Buddenbrock 1911; Marsh et al. 1992). After thirty or so such contractions the muscle becomes unexcitable and the shells remain closed through contraction of the smooth adductor muscle (Bayliss et al. 1930; Thompson et al. 1980).

Scallop and frog striated muscle exhibit similar isometric mechanical twitch kinetics, scallop fibres exhibiting mean half-times for tension rises of 43 msec (calcium release brought about by photolysis of nitr-5) (Lea et al. 1990) or 60 msec (electrical stimulation) (Rall 1981) as compared with 40 msec and 36 msec, respectively, for the frog. Twitch to tetanus ratios (Fig. 4.17) and heat coefficients are also similar (Rall 1981). This work suggested that the similarity of the isometric heat coefficients (force developed per unit energy liberated) indicates a basic similarity in mechanochemical conversion in scallop and frog striated muscle, assuming an unverified similarity between the *in vivo* enthalpy change for creatine phosphate and arginine phosphate hydrolysis (arginine phosphate, as opposed to creatine phosphate, is used as the back-up energy source in scallop striated muscle (De Zwaan et al. 1980)). Several distinct differences exist in the mechanics of these two muscles. The half-time taken for relaxation is significantly longer in scallop muscle (104 ± 2 msec) as opposed to the frog (66 ± 5 msec) under comparable conditions (Rall 1981). Figure 4.17 shows that scallop muscle develops about 50% less force than frog muscle, despite the similar twitch to tetanus ratio, an effect that may be more apparent than real: each small scallop muscle cell contains but a single myofibril surrounded by sarcoplasmic reticulum and sarcolemma, yet force is normalised per unit area; it may be that, in aggregate, a large area of scallop muscle is devoid of myofibrils, making the area comparison unrealistic. Scallop muscle also exhibits a dramatic fatigue during tetanus (Fig. 4.17; Rall 1981) and displays a greater post-tetanic twitch potentiation than frog muscle (Rall 1981), a feature of unknown significance.

For scallop striated muscle, the relationship between the development of isometric tension and calcium concentration, is very steep. In an activating solution containing 5 mM MgATP at pH 7.1 and 20°C, the rise in tension is completed between pCa values of 5.5 and 5.2 (Fig. 4.18a) giving rise to a Hill coefficient of 5.5 (Simmons and Szent-Gyorgyi 1985). When *in vitro* measurements of the relationship between actomyosin MgATPase and calcium concentration are compared under identical conditions with isometric tension measurements, the two sets of data superpose exactly (Fig. 4.18b;

Figure 4.17. Twitch and tetanus records from scallop (*Placopecten magellanicus*) (A) and frog (*Rana pipiens*) (B) muscle. Tetanus was for 1.5 s at 50 Hz. In C, the tetanic contractions were scaled to the same peak value. Records reproduced, with permission of the publisher, from Rall 1981.

Chantler et al. 1981; Simmons and Szent-Gyorgyi 1985). The high value of the Hill coefficient obtained, as well as direct modelling of all possible ways calcium could activate a two-headed molecule (Chantler et al. 1981), indicated that an additional cooperative mechanism had to exist when myosin is associated within a thick filament, in order to account for the steepness of the activation curve with respect to calcium. It seemed likely that this was an intermolecular mechanism, propagated throughout the thick filament: full activation of one molecule allowing adjacent molecules to switch on both heads, even though only one head may have bound calcium (Chantler et al. 1981). This hypothesis has been substantiated further by structural studies on isolated scallop thick filaments which indicate that the ordered appearance, characteristic of the relaxed state, is lost over a very narrow range of free calcium concentrations upon activation (Vibert and Craig 1985). The structural basis for this intermolecular cooperativity may be related to a close interaction between pairs of heads arranged in helical strands along each half of the thick filament, one member of each pair coming from adjacent crossbridge levels (14.5 nm periodicity) (Levine et al. 1988; Levine 1993). Alternatively, it could be due to the interaction of heads at one crossbridge level with the underlying S-2 regions of myosin molecules located at the next crossbridge level along the filament.

4.5.2 The Interaction of Myosin with Actin

The interaction of myosin with actin in the presence of nucleotide is the process that lies at the core of muscle contraction: the crossbridge cycle. The *in vitro* equivalent of the crossbridge cycle is assumed, with appropriate caveats, to be the actomyosin kinetic cycle. A number of elementary steps in the scallop striated adductor myosin ATPase pathway

Figure 4.18. A). Relationship between isometric tension and calcium concentration (expressed as $pCa = -\log[Ca^{2+}]$). Tension was plotted relative to the value for pCa 4.88. The number of fibre bundles tested is given for each calcium concentration. The error bars are ± 1 S.E. of the mean. Inset: tension record from one fibre bundle; numbers are the pCa values. Figure reproduced, with permission of the publisher, from Simmons and Szent-Gyorgyi (1985). B). The *in vitro* response of *Placopecton* myofibrillar ATPase to calcium was compared directly to tension development of fibre bundles under identical conditions. Conditions were: 3 mM $MgCl_2$, 2 mM ATP, 30 mM NaCl, pH 7.0. For ATPase studies, the pH was maintained at pH 7.0 in a pH-stat; free calcium levels were determined by incremental addition of calcium to the above mixture containing 0.1 mM EGTA (x). Alternatively, the pH was maintained by a 15 mM imidazole buffer and the use of 1 mM CaEGTA/EGTA mixtures to achieve a particular pCa level (+). For tension studies (o), the latter buffer was used and methods similar to those in A) were employed. Tension measurements were performed by Prof. R. M. Simmons. Figure reproduced, with permission of the publisher, from Chantler et al. (1981).

are nearly identical to analogous steps in the rabbit myosin ATPase cycle (Taylor 1979). The principle difference is that in the scallop ATPase pathway, there is a marked suppression of the product dissociation steps in the absence of calcium (Jackson and Bagshaw 1988; Nyitrai et al. 2002). Such calcium sensitivity, exhibited by myosin alone (i.e., in the absence of actin), was originally noted by Ashiba et al. (1980) and further characterised by Wells and Bagshaw (1985); the latter workers showed that it was possible to separate the long-lived intermediate, formed in the presence of ATP and the absence of calcium, from unbound nucleotide using column centrifugation techniques. The long-lived intermediate was identified as M.ADP.Pi and the rate limiting step in the absence of calcium has been assigned to the phosphate release step (Wells and Bagshaw 1985; Jackson and Bagshaw 1988; Nyitrai et al. 2002).

A simplified version of the scallop myosin ATPase scheme is seen in Figure 4.19a. There are two calcium-sensitive steps: the rate-limiting dissociation of phosphate and the slow release of ADP (Wells and Bagshaw 1985; Jackson and Bagshaw 1988; Nyitrai et al. 2002). The fact that there are two calcium-sensitive elementary steps may have some significance with regard the catch mechanism (see below). The dissociation of ADP is depicted as a single step in Figure 4.19a; in reality it will consist of a minimum of two

Figure 4.19. A. Elementary steps of the scallop myosin ATPase cycle both in the presence (Mc) and absence (M) of calcium. The majority of the data shown below were obtained for *Pecten maximus* HMM (Jackson and Bagshaw 1988) but where ranges are given they bracket data from *Pecten* as well as from *Argopecten irradians* and *Placopecten magellanicus* S-1 (Kurzawa-Goertz et al. 1998). Most rate constants were determined in 20 mM NaCl, 1 mM MgCl₂, 10 mM TES, 0.1 mM EGTA, pH 7.5, 20°C ± 0.2 mM CaCl₂ and were: $k_{+1} = 2.5 \times 10^6 \text{ M}^{-1}\text{s}^{-1}$; $k_{+2} = 200 \text{ s}^{-1}$; $k_{+3} = 0.002 \text{ s}^{-1}$; $k_{+4} = 0.01 \text{ s}^{-1}$; $k_{c+1} = 2.5 \times 10^6 \text{ M}^{-1}\text{s}^{-1}$; $k_{c+2} = 200 \text{ s}^{-1}$; $k_{c+3} = 0.2 \text{ s}^{-1}$; $k_{c+4} = 6 \text{ s}^{-1}$; $k_a = k_{c+4} = 8 \times 10^5 \text{ M}^{-1}\text{s}^{-1}$; $k_b = 25 \text{ s}^{-1}$; $k_c = 2.5 \times 10^8 \text{ M}^{-1}\text{s}^{-1}$. B. Summary of product release steps for the acto-HMM ATPase. Conditions used were as for A. Of the equilibrium constants shown, K₃ and K₄ are calcium insensitive whereas K₁ and K₂ are calcium sensitive (Stanners and Bagshaw 1987). For S-1, K₁ = $1.2 \times 10^5 \text{ M}^{-1}$; K₂ = $5.7 \times 10^{-4} \text{ M}$; K₃ = $2.5 \times 10^4 \text{ M}^{-1}$; K₄ = $4.5 \times 10^{-7} \text{ M}$ (Kurzawa-Goertz et al. 1998), where the equilibrium constants are defined in a clockwise direction in scheme B (i.e., K₁.K₂.K₃.K₄ = 1).

steps, the dissociation ultimately occurring via a weakly-bound intermediate. Equilibrium binding studies have shown that ADP binds scallop HMM more strongly in the absence of calcium than in its presence (Wells et al. 1985; Kalabokis and Szent-Gyorgyi 1997) and the conformation of the myosin head upon binding ADP would also appear to be calcium-dependent (Jackson and Bagshaw 1988; Stafford et al. 2001).

The binding of ATP and its subsequent hydrolysis takes place in a series of fast, coupled steps that are similar in both vertebrate and invertebrate striated muscle. ATP binding is at least a two-step process involving the formation of a collision intermediate followed by a conformational change; all binding transitions are subsumed into a single step in Figure 4.19a. Experiments on *Dictyostelium* myosin constructs have shown that tryptophan fluorescence (Trp509 in the *Pecten* sequence) can be used to discriminate kinetically between the hydrolysis step and the closure of the 50 kDa jaws (see Fig. 4.14) (Malnasi-Csizmadia et al. 2000). The cleavage step is rapid and leads to the formation of enzyme-bound products (the so-called early phosphate burst). By analogy with the vertebrate myosin kinetic scheme (e.g., Adelstein and Eisenberg 1980), the hydrolysis step will have an equilibrium constant in the region of 1–10, ensuring a minimal decrease in free energy during nucleotide cleavage. The largest drop in free energy in the cycle accompanies phosphate release.

All the intermediates of the scheme depicted in Figure 4.19a, in the presence and absence of calcium, are expected to be in rapid equilibrium with actin at intermediate and high actin concentrations (Stein et al. 1979; Taylor 1979; Adelstein and Eisenberg 1980; Nyitrai et al. 2003). Calcium does not regulate the affinity of actin for scallop myosin heads in the absence of nucleotide (Nyitrai et al. 2003) or in the presence of excess ATP (Chalovich et al. 1984; Nyitrai et al. 2003). The latter results were shown by comparing actin-activated ATPase rates and the degree of binding of actin to HMM as a function of actin concentration, in the presence and absence of calcium, under identical conditions. At high actin concentrations, where most of the HMM was bound, the rate of ATP hydrolysis remained inhibited in the absence of calcium (Chalovich et al. 1984). These results were the first to imply that calcium must exert its control on attached intermediates of the kinetic cycle. Constants obtained (25°C, pH 7.0) were: for HMM(+Ca²⁺), $V_{\max} = 14 \text{ s}^{-1}$, $K_{\text{ATPase}} = 3.1 \times 10^4 \text{ M}^{-1}$, $K_{\text{binding}} = 2.1 \times 10^4 \text{ M}^{-1}$; for HMM(-Ca²⁺), $V_{\max} = 3 \text{ s}^{-1}$, $K_{\text{ATPase}} = 2.4 \times 10^4 \text{ M}^{-1}$, $K_{\text{binding}} = 4.1 \times 10^3 \text{ M}^{-1}$; for Ca.Mg S-1 (irrespective of calcium levels), $V_{\max} = 15 \text{ s}^{-1}$, $K_{\text{ATPase}} = 3.7 \times 10^4 \text{ M}^{-1}$, $K_{\text{binding}} = 4.4 \times 10^4 \text{ M}^{-1}$.

The 5-fold sensitivity to calcium exhibited by the K_{binding} data compared with the virtual calcium insensitivity of the K_{ATPase} data led Chalovich et al. (1984) to discuss the possibility that the true value of K_{ATPase} was being obscured by a small population of calcium-insensitive molecules that possessed an elevated actin-activated ATPase at all times. This was proven to be the case by elegant studies involving measurements taken during single or limited turnovers of ATP hydrolysis whilst monitoring turbidity (Wells and Bagshaw 1984; Jackson et al. 1986; Ankrett et al. 1991b) or fluorescence (Wells et al. 1985; Jackson and Bagshaw 1988; Walmsley et al. 1990; Ankrett et al. 1991b) as a measure of complex formation between actin and HMM. These experiments established that the calcium sensitivity of fully regulated molecules could be as much as 650-fold at low ionic strength *in vitro* (Wells and Bagshaw 1984). As routinely prepared, between 10

and 30% of scallop HMM molecules are calcium insensitive, a fact which hampered earlier attempts to measure the rates of elementary steps of the scallop actomyosin ATPase scheme in the absence of calcium and has led to the exercise of considerable ingenuity in the design of experiments.

Direct interpretation of experiments using transient kinetics became possible with the advent of a method for preparing low yields of fully active, calcium-sensitive scallop HMM (Kalabokis and Szent-Gyorgyi 1997). These data, obtained using HMM prepared from *Argopecten irradians* (Nyitrai et al. 2002), yielded rate constants in agreement with the earlier studies on HMM from *Pecten maximus* (Jackson and Bagshaw 1988). Furthermore, apart from the calcium sensitive steps, individual rate constants were in agreement with those obtained from calcium insensitive *Argopecten irradians* S-1 (Kurzawa-Goertz et al. 1998) reinforcing the idea that individual activated heads act independently from each other. However, the data obtained from the improved HMM preparation also extended our knowledge in several important ways. As noted above, calcium does not regulate the affinity of actin for scallop myosin heads in the absence of nucleotide or in the presence of ATP; however, ADP binding (Nyitrai et al. 2002) and actin affinity in the presence of ADP (Nyitrai et al. 2003) are calcium dependent. Detailed analysis indicates that k_{+4} is about 20-fold smaller than k_{+4}^c (Fig. 4.19a). Conversely, the reverse steps are calcium insensitive, k_{-4} taking the same value as k_{-4}^c . This, together with the calcium-sensitive phosphate dissociation step, accounts for the effect of calcium on scallop HMM kinetics. Access to the nucleotide pocket in the absence of calcium is not a problem because ATP was able to displace a fluorescent form of ADP (mant-ADP) with an identical dissociation constant to that in the presence of calcium; instead the off-state of the myosin head is stabilised by ADP in the absence of calcium. This off-state, at ADP concentrations below 50 μ M for scallop HMM, requires only an occupancy of one ADP per two-headed molecule (Nyitrai et al. 2002), an observation consistent with an asymmetric structure during the maintenance of the off-state (see discussion above and Colegrave et al. 2003). Based on their detailed kinetic results, Geeves and coworkers proposed a classic Monod-Wyman-Changeux cooperative model (Monod et al. 1965) to account for the cooperative activation of scallop myosin by calcium in the presence of nucleotide (Nyitrai et al. 2002). In this model, the heads of scallop myosin exist in an equilibrium between "off" and "on" conformations, even in the absence of nucleotides and calcium where 30% of the heads are in the off-state. When one head is occupied by ADP, it spends 90% of its time in the off-state. Addition of one calcium ion to this ADP-bound state switches the equilibrium to 45% on; a full complement of bound calcium shifts the balance to 88% on (Nyitrai et al. 2002).

Using pyrene-labelled actin as a binding-sensitive fluorescence probe, the dissociation and association rate constants of actin and scallop HMM have been measured in the absence of nucleotide and shown to be calcium independent (equilibrium constant K_4 in Fig. 4.19b) (Wells and Bagshaw 1984; Stanners and Bagshaw 1987). ATP-induced dissociation of HMM from pyrene-actin was also calcium independent (Nyitrai et al. 2003). Titration of the fluorescence amplitude during binding indicated that the rigor complex of scallop HMM with actin requires both heads in a 1:1 head to actin stoichiometric ratio, each head tightly bound with an affinity <5 nM in the presence and

absence of calcium (Nyitrai et al. 2003). In the absence of calcium and the presence of ADP, the heads do not bind actin to any significant degree (Nyitrai et al. 2003); this fact pre-empted determination of which head – the one with or without ADP – is able to interact with actin (see Fig. 4.16b). Because the binding of myosin heads to actin in the presence of ATP appears to be calcium insensitive (equilibrium constant K_3 in Fig. 4.19b) (Chalovich et al. 1984; Wells and Bagshaw 1984; Nyitrai et al. 2003), yet product dissociation from unbound myosin is calcium-sensitive (equilibrium constant K_1 in Figure 4.19b) (Wells and Bagshaw 1985; Nyitrai et al. 2002), it can be reasoned on thermodynamic grounds from the product release steps shown in Fig. 4.19b, that the dissociation of products from heads already attached to actin must be calcium-sensitive (equilibrium constant K_2 in Fig. 4.19b) (Stanners and Bagshaw 1987). The long-lived intermediate present in relaxed scallop striated adductor myofibrils is known to possess ADP (Marston and Lehman 1974; Wells and Bagshaw 1985) so, by analogy with the vertebrate actomyosin ATPase scheme (Adelstein and Eisenberg 1980; Taylor 1979) as well as the scallop myosin ATPase cycle (Jackson and Bagshaw 1988), it seems likely that the rate is limited by loss of products from the A.M.ADP.Pi state, phosphate dissociation being the favoured limiting factor. This rate, for HMM, is elevated >600-fold in the presence of calcium (Wells and Bagshaw 1985; Stanners and Bagshaw 1987); in the case of acto.S-1 (equivalent to the on-state of HMM), the rate of ADP release proved too fast to measure (>200 s⁻¹) (Kurzawa-Goertz et al. 1998). In the presence of calcium, ADP and actin bring about reciprocal lowering of the other's affinity for HMM by 30–50-fold, yet the heads still remain in the associated state (Nyitrai et al. 2003). Effectively, ADP and actin mutually exclude each other from binding to HMM.

4.5.3 The Crossbridge Cycle

For several decades prior to atomic resolution of the structures involved, our working model of the crossbridge cycle was framed by a handful of influential contributions (Huxley 1957; Huxley 1969; Huxley and Simmons 1971). In the advent of structural knowledge at atomic resolution (Rayment et al. 1993a; Rayment et al. 1993b; Geeves and Holmes 1999; Houdusse et al. 2000) these ideas have been reformulated with increased precision. The crossbridge is defined as that working portion of the myosin molecule – the head (motor domain) plus neck (lever arm) and possibly a portion of the tail (HMM S-2) – capable of reaching out from the muscle thick filament so as to interact with actin in a stochastic and asynchronous manner, participating in a repetitive cycle comprising attached and detached states. Each crank of the cycle is thought to be powered by the hydrolysis of a single molecule of ATP (Toyoshima et al. 1990; Ishijima et al. 1998), though contrary views exist (Harada et al. 1990; Kitamura et al. 1999). Conventional muscle myosin is a non-processive motor with a low duty ratio (Howard 1997): i.e., the majority of the cycle time is spent during an obligatory period of detachment (Linari et al. 1998). Vertebrate myosin step sizes have been measured through a variety of techniques and the values obtained are likely to be similar for scallop myosins. Measurements vary from 4–15 nm (Uyeda et al. 1991; Molloy et al. 1995; Ishijima et al. 1998; Kitamura et al. 1999) to >100 nm (Yanagida et al. 1985; Harada et al. 1990; Sellers and Homsher 1991);

measurements made using compliant optical traps are likely to be most accurate and are in the range 4–15 nm (Mehta et al. 1999); within this spread, 4–6 nm is considered to be the most likely length of a single step. This narrow range encompasses results from mechanical experiments which show that tension in an active muscle can be reduced to zero upon rapid shortening by only 4–6 nm per half sarcomere (Huxley and Simmons 1971). Force is generated by the attached crossbridge pulling the thin filaments in the direction required for sarcomere/muscle shortening or for the maintenance of isometric force. Estimates of the average force generated by a single head under isometric conditions are in the range, 1–4 pN (Molloy et al. 1995; Block 1996). Both tilting of the myosin head and rotation of part of the lever arm have been observed during contraction through the application of spectroscopic techniques simultaneously with mechanochemical measurements (Irving et al. 1995; Baker et al. 1998; Corrie et al. 1999). In the case of smooth muscle myosin heads, structural analysis has provided evidence for a 3.5 nm movement upon ADP release (Whittaker et al. 1995). In general, the short range of the step size (<15 nm) together with the low duty ratio (<20%) suggests that individual myosin heads will only generate contractile force when appropriately oriented actin monomers become accessible, at integral values of the half pitch (36–37 nm) of the actin helix (Howard 1997). Thus, although the action of any single head may only be responsible for 4–6 nm of movement per half sarcomere, which would not in itself facilitate immediate rebinding, each head is placed within its appropriate target area with respect to the next actin binding site through the collective actions of hundreds of other heads within each bipolar filament.

The marriage of crossbridge mechanics and solution kinetics has illuminated our thinking on aspects of this cyclic mechanism (Eisenberg and Greene 1980; Eisenberg and Hill 1985; Hibberd and Trentham 1986; Cooke 1997; Goldman 1998; Geeves and Holmes 1999). Figure 4.20a depicts a clear, conceptual, one-to-one correlation between steps in the actomyosin ATPase cycle and possible orientations of the crossbridge. While oversimplistic, it has heuristic value for it illustrates a minimal structural scheme necessary to account for crossbridge cycling which, together with a minimal ATPase scheme (Fig. 4.20b), describe events that occur in solution at low actin concentration (Lymn and Taylor 1971). In this scheme, one ATP is hydrolysed per round of cycle; ATP binding causes detachment of the myosin head from actin followed by rapid hydrolysis of ATP on the detached head, bringing about a putative change in conformation which cocks the mechanism; the power-stroke (step 4) corresponds to the rate-limiting product release step(s) which are assumed to be accompanied by a large drop in free energy (Adelstein and Eisenberg 1980); in this scheme the cycle is completed by the generation of the 45° state rigor complex, poised to take up ATP once again.

In vitro experiments conducted at the high concentrations of actin approaching those present in muscle have suggested that all intermediates of the myosin ATPase pathway could be in rapid equilibrium with their actin-bound states and that hydrolysis of ATP could occur in the attached state (Stein et al. 1979; Adelstein and Eisenberg 1980; Eisenberg and Hill 1985). Although evidence in support of such rapid equilibria has been obtained in relaxed muscle (Brenner et al. 1982) myosin heads are known to be dissociated from actin for a considerable portion of the ATPase cycle (Linari et al. 1998).

Figure 4.20. a). Schematic diagram of simplified structural features of the crossbridge cycle of muscle contraction (after Lymn and Taylor 1971). b). Basic kinetic scheme of the fundamental biochemical species that are thought to correlate with the structural events in a) (after Lymn and Taylor 1971). c). Schematic diagram combining both structural and biochemical features of the crossbridge cycle. Whilst more complicated than either a) or b), it is likely to be more realistic. The 90° states $M.ATP$, $M.ADP.P_iI$, and $M.ADP.P_iII$ are in rapid equilibrium with $A.M.ATP$, $A.M.ADP.P_iI$, and $A.M.ADP.P_iII$, respectively. The motional transition does not have an activation energy or a rate constant. It is a continuous conformational change that occurs as the filaments slide past each other. It is the second step of a transition from the unstrained 90° conformation to the unstrained 45° conformation; the first step involves P_i release and has both an activation energy and a rate constant. a) and b) taken, with permission of the publisher, from Offer, G. 1974. In: A.T. Bull et al. (Eds.). Companion to Biochemistry: Selected Topics for Further Study. Longman, London. c) reproduced, with permission of the publisher, from Eisenberg and Hill (1985).

Consequently, hydrolysis is still envisaged as taking place on dissociated myosin heads and this step contributes to part of the cycle time (White et al. 1997). A more realistic scheme involving strongly bound states such as AM and AM.ADP, and weakly bound states such as AM.ATP and AM.ADP.Pi, is seen in Fig. 4.20c. In this scheme, different myosin intermediates will have distinct preferential angles of attachment to actin; two such angles (45° and 90°) are shown here and their structural counterparts have been identified in scallop myosin (Houdusse et al. 2000) (see Fig. 4.21). It is possible that each state of myosin can bind to actin through a variety of angles, the probability of attachment or detachment being determined by a free energy profile in each case. Indeed, a number of pre-power stroke attachment angles have been inferred from fluorescence energy transfer (Shih et al. 2000) and electron spin resonance (Roopnarine et al. 1999) spectroscopic approaches, the latter using adductor muscle fibres from *Placopecten magellanicus*. All rate constants in the cycle (Fig. 4.20c) are assumed to be sensitive to mechanical strain in the crossbridge (Eisenberg and Hill 1985).

As noted above (see Fig. 4.14) three conformational states of the scallop myosin head have been determined so far and these have provided mechanistic insights into the hydrolysis of ATP. Critical for the interaction with actin is the key observation that when all three structures are compared in a view where each actin-binding interface is constant, the structures differ dramatically with regard to the disposition of their lever arms – which could be taken as a glimpse of three still pictures at different stages within the crossbridge cycle (Houdusse et al. 2000). In state I, the lever arm appears to be at an angle close to the rigor bond angle of 45° in the chicken skeletal structure (Rayment et al. 1993b) but is closer to 25° in scallop state I (Houdusse et al. 2000). In state II, this angle has changed to close to 90° (Dominguez et al. 1998; Houdusse et al. 2000). State III is different again, the lever arm making an angle of only around 15° to the actin filament (Houdusse et al. 1999) (Fig. 4.21a). State III is also remarkable in providing structural confirmation of a long-known biochemical observation (Reisler et al. 1974; Wells and Yount 1980; Huston et al. 1988) – the α -helix connecting the reactive thiols, SH1 (*Pecten* C706) and SH2 (*Pecten* C696), melts upon nucleotide hydrolysis, bringing these residues to within 0.7 nm of each other, facilitating chemical crosslinking (in states I and II these residues point in opposite directions at extreme ends of the SH α -helix, obviating crosslinking). There is also an overall rotation of the converter domain within the state III structure through angles of $\sim 30^\circ$ and 90° , as compared with the state I and state II structures, respectively (Houdusse et al. 1999; Houdusse et al. 2000). The step size, as deduced from these structural considerations, is ~ 12 nm (Houdusse et al. 2000).

While it is tempting to correlate the three states seen in Fig. 4.21a with the various stages of the crossbridge cycle, extreme caution must be taken. State I, while ostensibly free of nucleotide, has been attained with a sulphate ion at the active site (Rayment et al. 1993a); furthermore, the same structure has been observed in the presence of ATP analogs (Gulick et al. 1997) or ADP (Houdusse et al. 2000). Therefore, there is some ambiguity associated with this state – it has been referred to variously as a weak-binding, pre-hydrolysis state (Gulick and Rayment 1997) or, alternatively, as a near-rigor conformation (Houdusse et al. 2000). State II, crystallised in the presence of MgADP.AIF_4^- (Fisher et al. 1995; Dominguez et al. 1998) or MgADP.VO_4 (Smith and Rayment 1996; Houdusse et

Figure 4.21. a) Illustration of the three distinct positions of the lever arm as defined from the three known conformational states of scallop myosin. These compare the nucleotide-free state (state I); the transition state (ADP·VO₄) (state II); the detached state (ADP) (state III). Ribbon diagrams oriented so as to superpose the conformation of the lower 50 kDa domain in all three states. Vertical arrow indicates the approximate direction of the actin axis. The end of the lever arm moves about 12 nm between states II and III and exhibits a small azimuthal displacement. Figure taken from Houdusse et al. (2000) and reproduced here with permission from the publisher. b) and c) Alternative analysis based on data from *Dictyostelium* myosin head structures showing the interaction of myosin heads, in either the closed (b) or open (c) conformations, with the actin filament structure. The CLOSED (ADP·VO₄) (Smith and Rayment 1996) and OPEN (ADP·BeF₃) (Fisher et al. 1995) conformations are thought to represent the pre-power-stroke and post-power-stroke states, respectively. The terms CLOSED and OPEN derive from whether or not the backdoor γ -phosphate release mechanism is closed or open and from the disposition of the switch II helix (Smith and Rayment 1996; Geeves and Holmes 1999). The end of the lever arm moves about 11 nm between the two states. Figures kindly provided by Prof. Ken Holmes and reproduced from Geeves and Holmes (1999) with permission of the publishers.

al. 2000) is a transition state intermediate and therefore represents a weak-binding, pre-hydrolysis state (Fig. 4.21a, b). Although state III was crystallised in the presence of ADP, the investigators suggest that it is actually another weak-binding state (Houdusse et al. 1999); in support of this, S-1 preparations in which SH1 and SH2 are crosslinked together with *para*-phenylene dimaleimide (pPDM) are well-characterised as having a weak affinity for actin (Chalovich et al. 1983). Consequently, strong binding state intermediates, responsible for actin-induced ADP release (see Fig. 4.20c) appear to be missing (Geeves and Holmes 1999; Houdusse et al. 2000). Because it will be difficult, if not impossible, to crystallise these fragments while bound to actin, the identification of strong binding states in isolation remains a problem. Crystals of *Dictyostelium* myosin heads possessing the bipyrimidal MgADP.VO_4 ion at the active site (Smith and Rayment 1996), together with the MgADP.AIF_4^- containing fragments (Fisher et al. 1995; Domínguez et al. 1998), have been interpreted as representing pre-power-stroke structures (Geeves and Holmes 1999). The γ -phosphate binding pocket in these structures is in a “closed” state and the disposition of switch II is altered substantially relative to the nucleotide-free structure (Fig. 4.21b). Geeves and Holmes (1999) modelled this structure bound to an F-actin filament and showed that the displacement of the working stroke of the tail, from the “up” to the “down” position, occurred when the γ -phosphate binding pocket changed from the “closed” to an “open” configuration, consequential to an inward movement of switch II. The open configuration is deduced from myosin heads crystallised in the presence of MgADP.BeF_3 (Fisher et al. 1995) and is thought to define the post-power-stroke structure while bound to F-actin (Fig. 4.21c).

It is not entirely clear that all structures depicted in Fig. 4.21 are truly intermediates of the cycle. For example, state III could represent a weakened dragged-bridge that had failed to dissociate at the end of the cycle (Sellers and Homsher 1991; Cooke 1999). Also, the relaxed state may not necessarily be equivalent to a state within the crossbridge cycle: the time-course of activation of ABRM muscle suggests that during relaxation, the heads reside close to the thick filament and, upon activation, must first swing out towards the filament (Lowy and Poulsen 1987). Furthermore, under the conditions that pertain in muscle, it is likely that ATP can bind to myosin faster than the initial actomyosin state can revert to the rigor configuration. Consequently, the rigor state is not necessarily equivalent to a state within the crossbridge cycle. Clearly, although there has been much progress, there is more to learn.

4.5.4 Myosin-linked Regulation

In the absence of calcium, tension generation by the striated adductor muscle, as well as the Mg^{2+} -ATPase in the presence or absence of actin, and actin-dependent motility, are all repressed. An increase of calcium above micromolar levels elevates these activities by 100–1000 -fold. In scallop striated adductor muscle, this control is exerted through the action of regulatory myosin; upon activation calcium ions bind to specific sites, one on each head of myosin, and sensitise the molecule so that it can interact with actin (Kendrick-Jones et al. 1970; Kendrick-Jones et al. 1976; Chantler and Szent-Gyorgyi 1980; Chantler et al. 1981). In scallop smooth adductor muscle, myosin phosphorylation

mechanisms may occur in addition to activation by direct calcium binding (Sohma et al. 1985; Castellani and Cohen 1987a; Takahashi et al. 1988). Myosin-linked regulation in the scallop contractile system has been demonstrated at the level of the myosin molecule alone (Ashiba et al. 1980; Wells and Bagshaw 1985; Nyitrai et al. 2002); actomyosin (or acto-HMM) in ATPase assays (Chantler et al. 1981; Wells and Bagshaw 1984; Ankrett et al. 1991b; Nyitrai et al. 2003) or motility assays (Vale et al. 1984; Colegrave et al. 2003); myofibrils (Kendrick-Jones et al. 1970; Kendrick-Jones et al. 1976; Chantler and Szent-Gyorgyi 1980) and muscle fibres (Simmons and Szent-Gyorgyi 1978; Kerrick et al. 1981; Lea et al. 1990). Myosin-linked control is considered to be the dominant form of regulation in scallop adductor muscles because specific removal of regulatory light chains (R-LCs) abolishes regulation in both myofibrils (Szent-Gyorgyi et al. 1973; Chantler and Szent-Gyorgyi 1980) and fibres (Simmons and Szent-Gyorgyi 1978; Simmons and Szent-Gyorgyi 1985); full regulation is restored upon readdition of a stoichiometric amount of pure R-LCs (Kendrick-Jones et al. 1976; Chantler and Szent-Gyorgyi 1980; Simmons and Szent-Gyorgyi 1985). Although it is plausible that the desensitisation procedure may also remove troponin components, it is known that troponin molecules are present in sub-stoichiometric amounts in muscles from many species of scallop and a functional "relaxing factor", isolated from purified adductor thin filaments, has been difficult to demonstrate in these species (see above). Furthermore, scallop myofibrils do not show a significant increase in ATPase activity in the presence of low concentrations of ATP and an absence of calcium (Knox et al. 1986), characteristics that would be expected of myofibrils extracted from muscles exhibiting thin-filament linked regulation. However, it is not possible to rule out a contribution from a small population of thin-filament regulated (or dually regulated) fibres, whose function is critically impaired by extraction procedures or EDTA treatment.

Calcium-specific binding to scallop striated adductor myosin, measured at 25° in the presence or absence of MgATP at low ionic strength, follows a simple binding isotherm and yields association constants close to 10^7 M^{-1} at pH 7.5 and 10^6 M^{-1} at pH 7.0 (Chantler et al. 1981). However, at physiological ionic strength or in the presence of MgADP or nucleotide analogs, calcium binds cooperatively, exhibiting Hill coefficients in the range 1.6–2.8 (Kalabokis and Szent-Gyorgyi 1997). In the presence of 1 μM calcium, 2 mM magnesium $\pm$ 1 mM ATP scallop myosin binds two calcium ions per molecule (Chantler and Szent-Gyorgyi 1980; Chantler et al. 1981; Kalabokis and Szent-Gyorgyi 1997). The association and dissociation steps for this process are extremely rapid, yielding rates of the order of $>10^8 \text{ M}^{-1} \text{ s}^{-1}$ and 25 s^{-1} , respectively (Jackson and Bagshaw 1988). The measured dissociation rate constant is at least 30 x faster than the rate of dissociation of calcium ions from the non-specific divalent cation site located on each R-LC (Bagshaw and Reed 1977; Bennett and Bagshaw 1986a). Magnesium dissociates from the non-specific sites at an even slower rate (0.05 s^{-1}) (Bennett and Bagshaw 1986a). Consequently, it is only the calcium-specific site that displays appropriate kinetics to account for the rapid activation characteristic of scallop adductor muscles, which approach peak tension within 90 msec of stimulation (Rall 1981).

Isolation of the regulatory domain (RD) – the light chain binding fragment of the myosin heavy chain (MHC), together with associated light chains – has provided

significant insights into myosin-linked regulation. Earlier small-scale tryptic preparations (Bennett et al. 1984; Szentkiralyi 1984) have been improved to generate high yield preparations, either through the direct use of trypsin (Kalabokis et al. 1994) or the sequential use of papain and clostripain (Kwon et al. 1990; Xie et al. 1994). More recently, both *Argopecten* (Malnasi-Csizmadia et al. 1999) and *Pecten* (Janes et al. 2000) RDs have been isolated following peptide expression from bacterial constructs. The RD complex exhibits calcium-specific binding, albeit of slightly lower affinity than the parent myosin molecule (Kwon et al. 1990) accompanied by a characteristic, reversible increase in intrinsic tryptophan fluorescence (Wells et al. 1985; Malnasi-Csizmadia et al. 1999; Janes et al. 2000), the increased emission arising mainly from Trp21 of the essential light chain (E-LC) (Malnasi-Csizmadia et al. 1999). Construction of hybrid RDs produced the first significant evidence in favour of a direct role for the E-LC in calcium-specific binding (Kwon et al. 1990) and showed that the primary calcium-binding capacity of this light chain could be modified by the source of heavy chain with which it was associated (Kalabokis et al. 1994). Crystallisation of the RD (Fig. 4.15) provided high resolution images of this critical regulatory region of the myosin molecule (Xie et al. 1994; Houdusse and Cohen 1996). The minimalist structures of the early proteolytic fragments (*Argopecten* MHC fragment 775–840) (Kalabokis et al. 1994) can now be extended at will in the amino-terminal (Janes et al. 2000) or carboxyl-terminal (Malnasi-Csizmadia et al. 1999) directions through recombinant techniques and bacterial expression. When the carboxyl terminal end is extended so as to include 48 heptad repeats of the myosin rod sequence (*Argopecten* MHC fragment 749–1175) dimerisation occurs leading to pairs of RD fragments joined together by a coiled-coil tail (Malnasi-Csizmadia et al. 1998). In the absence of RDs, the coiled-coil is unstable, a feature that may play a role during regulation (Malnasi-Csizmadia et al. 1998). Such lability may well underlie the generation of R-LC-R-LC dimers from *Mercenaria* R-LC hybrid scallop myosin molecules using the sulphhydryl-specific reagent, 5,5'-dithiobis (2-nitrobenzoic acid) (DTNB) (Bower et al. 1992). These results imply a transient propinquity of 2 Å even though modelling studies (Offer and Knight 1996) (which assume no such lability), crosslinking (Chantler and Bower 1988) and FRET (Chantler and Tao 1986; Chantler et al. 1991) data place the distance between these residues (position 50 on the scallop R-LC) as >15 Å. A partial unwinding of the proximal coiled-coil, facilitating passage of one chain over the other in this neck region of myosin, would bring the two *Mercenaria* cysteine residues into the required proximity. Evidence for such dynamic flexibility within the proximal coiled-coil has been inferred from experiments on vertebrate muscle myosin (Knight 1996).

Head-head cooperativity during actin-activation can be demonstrated either in solution, using scallop striated adductor HMM, or in suspension, using myosin filaments (Chantler et al. 1981; Walmsley et al. 1990; Kalabokis and Szent-Gyorgyi 1997; Nyitrai et al. 2002). Early work (Chantler et al. 1981) showed that two calcium ions must bind to both heads of HMM in order to switch the entire molecule on. Under the conditions of these experiments (40 mM ionic strength; 0–2.0 mM ATP; pH 7.0–7.5) calcium binding was characterised by a single binding isotherm, making it possible to predict the activation curve in a model-dependent manner (Chantler et al. 1981). This demonstrated a

cooperativity between the two heads of a single molecule during the activation process. As noted above, subsequent work has shown that if the ionic strength is raised to 170 mM or if the ATP is replaced by ADP, AMP-PNP or ADP-vanadate, calcium binding itself becomes cooperative (Kalabokis and Szent-Gyorgyi 1997), complicating interpretation of the activation curves under these conditions but now shown to be compatible with a classic Monod-Wyman-Changeux cooperative mechanism (Nyitrai et al. 2002). In turn, calcium decreases the affinity of ADP and AMP-PNP for myosin and HMM (Kalabokis and Szent-Gyorgyi 1997).

At low ionic strength, higher levels of cooperativity were detected for myosin filament activation than for soluble HMM (Hill coefficients ≥ 2.8) (Chantler et al. 1981; Kalabokis and Szent-Gyorgyi 1997). Furthermore, myosin ATPase data obtained *in vitro* as a function of free calcium (Chantler et al. 1981) superposed exactly on tension measurements made in the fibre under identical conditions (Fig. 4.18b) (Simmons and Szent-Gyorgyi 1985). Because the form of calcium dependence seen in the earlier work demonstrated a transition from a model where the binding of two calciums per myosin could switch the molecule on, to one where a single calcium would suffice (Chantler et al. 1981), the steep onset of activation was interpreted as indicating some form of intermolecular cooperativity operating between myosin molecules within each thick filament. This could be envisaged as occurring either through interactions between the heads of myosin molecules located at a single crown, or through interactions between heads in adjacent crowns (Fig. 4.6b) (Levine et al. 1988; Levine 1993). The recent development of HMM preparations demonstrating much greater levels of cooperativity (Kalabokis and Szent-Gyorgyi 1997), albeit still significantly less than myosin, raises the possibility that an intact HMM may be capable of duplicating the myosin data entirely. Unfortunately, attempts so far to prepare intact HMM through baculovirus expression have not yielded active preparations (Nyitrai, unpublished – as quoted in Perreault-Micale et al. 1996b; Janes 2001). Structural data remain suggestive of an intermolecular role (Levine 1993). At minimum, regulation must require a cooperative interaction between the two heads of each myosin molecule, which is modulated by the level of occupancy of the calcium and nucleotide binding sites within a thick filament.

Global structural changes, consequential to calcium binding, have been demonstrated using scallop myosin but their relationship to the regulatory process remains obscure. Similar to vertebrate smooth and non-muscle myosin II molecules (Craig et al. 1983), myosins from the striated adductor muscles of *Pecten maximus* (Ankrett et al. 1991a) and from both the striated and smooth adductors of *Patinopecten yessoensis* (Takahashi et al. 1989) have been shown to fold as 10S monomers under relaxing conditions. This effect has also been demonstrated on *Argopecten irradians* HMM (Frado and Craig 1992; Stafford et al. 2001). At physiological ionic strength, calcium binding promoted unfolding of 10S myosin to yield the extended 6S conformation (Takahashi et al. 1989; Ankrett et al. 1991a) but this transition was much slower than activation of product release by calcium binding (Ankrett et al. 1991a). Also, the regular arrangement of myosin heads seen at each crown within the thick filament under relaxing conditions becomes disorganised upon addition of calcium (Vibert and Craig 1985; Frado and Craig 1989). It is plausible that the head-head interactions promoted by nucleotide binding

under relaxing conditions become disrupted upon calcium binding, allowing the heads to act independently during the mechanochemical cycle (Kalabokis and Szent-Gyorgyi 1997).

What are the specific conformational changes that must supervene calcium-specific binding to a myosin head so as to trigger actin-activation? Although much detail is known regarding the structural changes undertaken at the active site during the catalytic cycle of an active myosin head (Rayment 1996; Houdusse et al. 2000), the structural changes involved in regulation remain subject to speculation for no myosin head has yet been crystallised in the “off-state”. We do know that calcium does not control actin binding directly (Chalovich et al. 1984) but brings about an elevation of nucleotide hydrolysis at the active site (Ashiba et al. 1980; Wells and Bagshaw 1985). Hence, the structural consequences of calcium-specific binding must be first transmitted to the active site, influencing the rate of product release; structural transitions that accompany ATP cleavage will facilitate actin-activation. Unfortunately, a sufficient number of snapshots of this dynamic process have yet to be collected in order to construct a detailed picture of how calcium-specific binding couples to events at the active site. But some clues do exist.

The role of the E-LC may be key to the mechanism of regulation. Structural studies (Xie et al. 1994; Houdusse and Cohen 1996), together with functional dissection through light chain point mutation and chimera construction (Jancso and Szent-Gyorgyi 1994; Fromherz and Szent-Gyorgyi 1995), have pinpointed the exact residues involved in calcium-specific binding within the N-terminal domain of the E-LC (see Myosin, above, and Figs. 4.12 and 4.15). However, it is possible that calcium-triggering is not the only function of the E-LC – it may also be physically involved in controlling events at the active site. Early evidence in support of this hypothesis was from antibodies, produced against the scallop E-LC, that had no effect on calcium-specific binding yet specifically increased the actin-activated ($-Ca^{2+}$) ATPase activity leaving the actin-activated ($+Ca^{2+}$) ATPase rate unaffected (Wallimann and Szent-Gyorgyi 1981). More recently, limited physical interactions have been seen between the C-terminal domain of the E-LC and the motor domain (Houdusse et al. 1999). This interface has been suggested to be a target upon the application of micromolar amounts of TFP to *Pecten maximus* myosin, myosin S-1 or myofibrils (Patel et al. 2000), eliminating ATPase hydrolysis by locking myosin in a form which may mimic the off-state. However, a hydrophobic patch associated with the lower 50 kDa subdomain of the heavy chain has been shown to be responsible for abrogation of ATPase activity in both conventional and unconventional myosins (Sellers et al. 2003), and may well be the main site of TFP inhibition in scallop myosin. Higher (millimolar) concentrations of TFP lead to dissociation of the R-LC (Patel et al. 2000), reminiscent of the effect of EDTA (Chantler and Szent-Gyorgyi 1980). The rate limiting step of the scallop myosin MgATPase, in the absence of calcium, is one which involves a weak-binding $ADP.P_i$ intermediate (Marston and Lehman 1974; Wells and Bagshaw 1985; Jackson and Bagshaw 1988). Importantly, the 25/50 kDa loop, which guards the entrance to active site cleft, is known to be a major determinant in the rate of ADP release (Spudich 1994; Perreault-Micale 1996b; Kurzawa-Goertz et al. 1998).

It is plausible that an association between the two heads of myosin in the off-state could be maintained by salt-bridge interactions between R-LCs located on adjacent heads

(Offer and Knight 1996), or through similar interactions which arise through head-head overlap between myosins molecules situated within adjacent crowns along helical arrays spiralling around each thick filament (Levine 1993). Alternatively, and more likely, asymmetric structures within the filament may maintain the off-state, similar to those described for smooth muscle where intramolecular interactions between the actin binding surface of one head and the converter domain of the adjacent head have been observed (Wendt et al. 1999; Wendt et al. 2001). Although two heads are required, this may not be sufficient to ensure regulation. Short-tailed HMM molecules from smooth muscle exhibit diminished regulation (Trybus 1994; Trybus et al. 1997); two-headed fragments require at least twenty heptads of coiled-coil in order to resist chain dissociation in either smooth (Trybus et al. 1997) or scallop (Malnasi-Csizmadia et al. 1998) myosin fragments and thereby maintain regulation or calcium-specific binding, respectively. However, it is also possible that the conformational relay mechanisms differ between scallop adductor and vertebrate smooth muscles (Patel et al. 2000). For instance, smooth muscle myosin (Kato and Morita 1996) and HMM (Trybus 1994) lacking E-LC has been shown to exhibit R-LC phosphorylation-dependent activation: an impossibility if the E-LC/motor domain interface is essential for regulation. Complete removal of E-LCs from either vertebrate (Wagner and Giniger 1981; Sivaramakrishnan and Burke 1982) or scallop (Ashiba and Szent-Gyorgyi 1985) myosins does not appear to perturb the intrinsic activity of the ATPase site – the presence of the E-LC is required in order to *curtail* activity in a regulatory myosin.

Clues to the next step in the conformational relay may be seen through examination of the structural locations of the regulation-sensitive residues identified within the primary scallop MHC sequence (Fig. 4.11) (Nyitrai et al. 1991). From the scallop S-1.ADP structure (state III) (Houdusse et al. 1999) Asp54 (numbering as for *Pecten*) is located on the surface of the SH3 domain, close to the point of contact with the E-LC; Trp35 and Gly42, while closer in primary sequence to the N-terminus than SH3, are located deeper in the molecule along a shallow cleft that separates the SH3 domain from the rest of the motor domain (note that residues 16–26 are invisible in the crystal structure (Houdusse et al. 1999) therefore the location of this mobile region is not clear). On the other side of this cleft, facing Trp35, are Glu96 and Ala97; it seems likely that interactions across this cleft represent the next turn of the cogs in this calcium-dependent conformational relay. It is of interest to note that the myosin head is so compliant that this cluster of regulation-sensitive residues is located on the opposite side of the molecule relative to the E-LC in the transition state structure (state II) (Dominguez et al. 1998). It remains unclear from either the state II or the state III structures as to exactly how the above regulation-sensitive residues communicate with the remaining two in the head, Glu184 and Lys188, which are close to the active site but several peptide layers removed from the other regulation-sensitive residues.

Examination of myosin head structures (Rayment et al. 1993a; Houdusse et al. 1999) indicates that results from earlier photo-crosslinking studies, which purported to show that a region of the R-LC could move relative to the E-LC in a nucleotide-dependent manner in the absence of calcium yet in a calcium-dependent manner in the presence of nucleotide (Hardwicke et al. 1983; Hardwicke and Szent-Gyorgyi 1985), were likely to originate

from intermolecular, rather than intramolecular events. Nevertheless, a calcium-dependent shift in the photolabelling of heavy chain residues by 2-[(4-azido-2-nitrophenyl)amino]ethyl diphosphate (NANDP), an ADP analog, has been observed (Kerwin and Yount. 1993). This altered labelling pattern is curious: Arg128, located close to the purine binding site, is labelled in the absence of calcium; yet in the presence of calcium Cys198 becomes labelled - a residue that is located some distance away from the nucleotide binding site, close to the surface of the molecule. If real, this suggests a dramatic and bizarre conformational change.

The functional link in the regulatory chain of command between the active site and the actin binding site appears to be the role of a single stretch of heavy-chain, switch II (Ile463-Asn472; numbering as for *Pecten*). Switch II lies at the base of the cleft that separates the 50 kDa region into upper and lower domains (Houdusse et al. 1999; Houdusse et al. 2000) and influences the shape of the cavity into which the nucleotide γ -phosphate fits. In both the nucleotide-free state I, and the detached state III, the jaws of the 50 kDa cleft are open (Fig. 4.14) yet the conformation of switch II remains unchanged. In the transition state II, switch II has moved towards the nucleotide binding site, partially closing the 50 kDa cleft and creating a distortion in the γ -phosphate bond, facilitating phosphate cleavage and possible subsequent departure by the "back door" (Fisher et al. 1995; Yount et al. 1995; Houdusse et al. 2000). All three flexible joints - switch II, the relay and the SH1 helix - respond in a coordinated manner to the cyclic hydrolysis of ATP during actin activation. Damage to the continuity of the α -carbon backbone in this critical region can abrogate actin activation, as demonstrated by proteolytic cleavage data. Digestion of scallop S-1(+LC) by trypsin leads to initial severance of the heavy-chain into 75 kDa N-terminal and 24 kDa C-terminal fragments (Szentkiralyi 1984; Szentkiralyi 1987), the cleavage probably occurring within the cluster of four lysine residues beginning at Lys636 (numbering as for *Pecten*). This uncouples actin-activation from the consequences of nucleotide cleavage at the active site, the former being abolished whilst the latter remains unaffected. If tryptic digestion is performed on scallop S-1(+LC) in the presence of excess actin, cleavage at this site is blocked. Instead, the primary cleavage site is found closer to the N-terminus, splitting the S-1 heavy-chain into 65 kD N-terminal and 31 kD C-terminal fragments (Szentkiralyi 1987), cleavage probably occurring at Lys547, Lys552, Lys560 or Arg562 (numbering as for *Pecten*). Such cleavage is unique to scallop myosin; severance of the S-1 heavy-chain at this site abolishes hydrolytic activity at the active site completely. Both sets of cleavage sites are within actin-associated regions of the lower 50 kDa domain; cleavage here would physically disconnect switch II and the relay from the SH1 helix.

In summary, regulation of scallop striated adductor contraction is accomplished by a complex allosteric mechanism. Myosin activation is triggered when calcium binds to calcium-specific sites located on the E-LC. The patency of this site is exquisitely maintained by the presence of the R-LC, hydrogen bonding from Gly117 being critical: when the R-LC is lost through divalent cation chelation, the E-LC can no longer bind calcium. Activation is cooperative; initially, calcium must bind to each site on *both* E-LCs of myosin in order to activate the molecule. The off-state is maintained through interactions between the two halves of the bipartite molecule, probably through an

asymmetric conformation. When a sufficient number (~20%) of myosins become activated within a filament, cooperativity increases and the mechanism changes such that both heads are activated by a single bound calcium per molecule. At physiological ionic strength in the presence of ADP, calcium binding itself is also cooperative. Subtle changes in bonding between adjacent peptide chains, close to the calcium binding site on the E-LC, transmit this triggering signal to the nucleotide binding pocket. Although this transmission could be through the MHC, it is also possible that it occurs via the C-terminal domain of the E-LC. When the myosin head is in the detached state III conformation, refractive to actin binding, suggestive links in the chain of command are found between the E-LC and SH3 on the myosin head, and across the cleft between SH3 and the heart of the motor domain, regulation-sensitive residues lining the way. The ensuing changes lead to an increase in the rate of loss of nucleotide cleavage products, the loss of γ -phosphate possibly being rate-limiting. ATP hydrolysis, facilitated by this conformational relay, leads in turn to precise changes which now prime the myosin head into state II, the "closed" transition state capable of binding to actin. In this state, regulation-sensitive residues are remote from the E-LC, bound nucleotide is present as a transition-state complex and the lever arm is cocked for the power-stroke. Actin binding increases the flux of nucleotide hydrolysis through the active site by causing reciprocal movements in switch II and the converter; the γ -phosphate leaves by the back door and ADP dissociates from the nucleotide pocket, while the lever arm swings and remains attached to actin, generating the "open" post-power-stroke state, state I. This cycle repeats for as long as calcium remains bound. Calcium dissociation favours a return to the actin-dissociated state, a nucleotide-bound head conformation which becomes locked in an associated state with an adjacent myosin head – the relaxed state.

4.6 FUNCTION OF THE SMOOTH ADDUCTOR

4.6.1 Physiology

Molluscan paramyosin-containing smooth muscles are capable of both tonic and phasic contraction. When the active state of a tonic contraction decays, such muscles may still sustain large tensions for long periods of time with little expenditure of energy. This stretch-resistant state is known as "catch" and is characterised by economy of energy usage during a period of extremely slow force decay (Jewell 1959; Nauss and Davies 1966; Baguet and Gillis 1968). Although considerable progress has been made, we are still far from understanding the catch state. Much of our knowledge of molluscan catch muscle physiology comes from the study of the anterior byssus retractor muscle (ABRM) of *Mytilus edulis*, an experimental preparation introduced by Winton (1937); there are practical difficulties in performing many of the requisite tension measurements on the more fragile scallop fibre preparations. Consequently, in the absence of evidence to the contrary, I will assume that facts obtained from studies on the ABRM apply equally to catch contraction in the scallop. A number of prior reviews have emphasised various aspects of the subject (Ruegg 1971; Twarog 1976; Achazi 1982; Chantler 1983; Muneoka and Twarog 1983; Watabe and Hartshorne 1990; Ruegg 1992).

Catch muscle is innervated by at least two types of nerve: cholinergic excitatory and serotonergic relaxing nerves. The firing of the excitatory nerve releases acetylcholine, which brings about catch contraction by eliciting a brief active contraction which decays to the catch state. Phasic contraction can be brought about most readily through addition of acetylcholine to the bathing medium (Fig. 4.22a; Jewell 1959; Ruegg 1965) or upon stimulation by an alternating current (Winton 1937). The immediate action of acetylcholine is to mediate the release of calcium from internal stores (Sugi and Suzuki 1978).

If, while the muscle is undergoing isometric contraction during the active state, a "quick release" is performed (i.e., one end of the muscle is released and the muscle is allowed to shorten by 5% of its length), the tension will drop momentarily and completely, owing to relaxation of the series elastic elements. Nevertheless, tension recovery under these conditions is rapid (Fig. 4.22a), demonstrating that the muscle is in the active state. By contrast, the catch state is induced in muscle fibres by specifically washing acetylcholine away from the bathing medium (Fig. 4.22b; Ruegg 1965) or by direct current stimulation (Winton 1937). A quick release performed under these conditions results in a rapid and complete loss of tension followed by negligible tension recovery (Jewell 1959), tension only being restored if the muscle is stretched back to its original length. This shows that the stiffness of this muscle is high and similar to that attained in the rigor state, except that nucleotide is present here: such an experiment demonstrates the catch state. Relaxation from catch is brought about by application of serotonin to muscle fibres in the bathing medium (Fig. 4.22c; Twarog and Cole 1973); applied serotonin has no effect during phasic contraction. Simultaneous application of serotonin and acetylcholine results in the phasic contraction of muscle fibres (Muneoka and Twarog 1983). *In vivo*, relaxing nerves are thought to release serotonin in order to abolish catch.

It would appear that the catch state can only be entered provided the muscle is primed by first passing through the active state. Thus, a brief application of acetylcholine or neural stimulation in the presence of serotonin antagonists will induce catch (Muneoka and Twarog 1983). Once the excitatory signal is removed, the high calcium levels elicited by the signal drop to low levels comparable with the relaxed state (Twarog 1967b; Atsumi and Sugi 1976). In the intact muscle, therefore, catch is a low calcium ($<10^{-8}$ M) state (Ishii et al. 1989).

Skinned fibre preparations have been very useful in extending our knowledge of the catch state (Baguet 1973; Marchand-Dumont and Baguet 1975; Cornelius 1980; Cornelius 1982; Pfitzer and Ruegg 1982). Such preparations lack a functional plasma membrane and sarcoplasmic reticulum; they are freely permeable to proteins and ligands added at will. With skinned fibres catch can be induced by calcium chelation (e.g., by addition of 20 mM EGTA in the presence of MgATP) following initiation of the active state (Fig. 4.22d) (Baguet and Marchand-Dumont 1975; Cornelius 1982; Pfitzer and Ruegg 1982; Castellani and Cohen 1987a; Siegman et al. 1997), further suggesting that active state priming and an absence of calcium are required to induce the catch state. The slow decline in tension (Fig. 4.22d) has been shown to correlate with negligible actomyosin ATPase activity (Guth et al. 1984). Quick release experiments provide results analogous

Figure 4.22. Physiological demonstration of the active and catch states in a molluscan muscle. A. Phasic isometric contraction of isolated anterior byssus retractor muscle (ABRM) of the bivalve, *Mytilus edulis*, after addition of 10 μ M acetylcholine to the bathing medium (seawater). A quick release of the muscle by 5% of its length (Δl) causes an immediate drop in tension (due to discharge of the series elastic elements) followed by active redevelopment of tension by the contractile elements. B. Isometric contraction induced by 10 μ M acetylcholine is terminated by washing out the drug (at arrow). During the very slow relaxation that follows, the ABRM is in catch. Tension is maintained passively. The active state is negligible, as indicated by the poor tension recovery following the quick release ($\Delta l = 5\% L_0$). Force is restored by restretching the fibres passively. C. Catch contraction of ABRM is induced by acetylcholine (first arrow) and then removed (second arrow). The slow relaxation which follows is accelerated by 10 μ M 5-hydroxytryptamine (third arrow), which abolishes catch without inhibiting active contraction. D. A catch-like state can be induced in chemically skinned preparations of ABRM by the initial addition of 20 μ M calcium (first arrow) followed by its removal (second arrow) upon addition of chelator. The slow relaxation that follows is accelerated by the addition of cAMP (10–100 μ M). A subsequent calcium-induced active contraction is only slightly inhibited by cAMP. All solutions contained 5 mM MgATP, 20 mM imidazole, pH 6.7. Data reproduced, with permission of the publisher, from Ruegg (1986).

to those described above, obtained on intact fibres. Using permeabilised fibres, the relaxing action of serotonin has been shown to be mimicked by cAMP (Cornelius 1982; Pfitzer and Ruegg 1982), by the catalytic subunit of cAMP-dependent protein kinase (Pfitzer and Ruegg 1982; Castellani and Cohen 1987a), NaF (Castellani and Cohen 1987a) and by ATP- γ -S (Castellani and Cohen 1987a); furthermore, fibre perfusion with the calcium-activated phosphatase, calcineurin, maintains the catch state under conditions that would otherwise lead to its decay (Castellani and Cohen 1992). Such results cannot be attributed to perturbations of calcium or calcium sensitivity and we are left with the ineluctable conclusion that pathways involving phosphorylation/dephosphorylation reactions are involved in the control of catch. The prime suspects to be considered as the major substrates for phosphorylation are paramyosin (Achazi 1979; Watabe et al. 1989), twitchin (Siegman et al. 1997; Siegman et al. 1998), myosin (Castellani and Cohen 1987a; Castellani and Cohen 1987b) and catchin (Yamada et al. 2000).

4.6.2 Catch Mechanism

There are two main contenders as possible explanations of the catch mechanism. While one theory holds that the catch state involves formation of actomyosin links which are somehow preserved, in the presence of nucleotide (Lowy and Millman 1963; Baguet and Gillis 1968), an alternative explanation takes more graphic account of the unique structure of the paramyosin-rich thick filaments and suggests a mechanism involving direct interactions between adjacent thick filaments (Johnson et al. 1959; Ruegg 1961; Gilloteaux and Baguet 1977). Although the ability to produce catch is synonymous with the presence of paramyosin-rich thick filaments in invertebrates, catch-like states have been described in vertebrate smooth muscles (Murphy et al. 1983; Hai and Murphy 1988), where it is termed "latch" owing to its similarity to "catch"; latch and catch may be mechanistically similar. Indeed, this similarity has been consolidated, recently, with the observation that catch forces may exist at higher than resting calcium concentrations (Butler et al. 1998; Siegman et al. 1998), similar to latch. Vertebrate smooth muscles do not contain paramyosin. Consequently, if the key intermediate of catch or latch is confined to regulatory step(s) of the crossbridge cycle, then the role for paramyosin in invertebrate muscles may simply be structural, related to the large size of the thick filaments, rather than being a critical component necessary for the generation of a high passive tension.

Earlier work appeared to substantiate the "paramyosin model" because a merging, or fusion, of thick filaments was observed in cross-sections of *Mytilus edulis* ABRM undergoing catch contraction (Heumann and Zebe 1968; Gilloteaux and Baguet 1977; Hauck and Achazi 1987). However, these data have been criticised (Bennett and Elliott 1989) on two grounds – first, that events occurring within the muscle between the times of fixation and observation were largely uncontrolled, and second, that inter-filament crosslinking artefacts could occur during the fixation process. To overcome such drawbacks and arrest ABRM in a defined state of catch, Bennett and Elliott (1989) used freeze-substitution prior to electron microscopy, measuring mechanical properties of the muscle up until the instant of slam-freezing, thereby fixing the muscle instantaneously

relative to the time-scale of the catch mechanism. Under these conditions, no evidence for thick filament clumping during catch was obtained; instead, well-separated thick filaments were found, surrounded by partial rings of thin filaments, the thick and thin filaments sometimes being closer to each other than during phasic contraction. These authors could only reproduce micrographs showing clumped thick filaments if cell membranes were badly damaged. The work of Bennett and Elliott (1989) represents the best ultrastructural evidence so far in favour of catch being a consequence of an altered actomyosin association rather than through thick filament interaction.

Although paramyosin may not play a direct role in the maintenance of catch, an indirect role in addition to its contribution to structure is more difficult to rule out. Paramyosin extracted from serotonin-treated muscles is able to incorporate two to four times as much covalently bound phosphate as paramyosin extracted from untreated or acetylcholine-treated muscles (Achazi 1979). This observation is consistent with a greater degree of paramyosin phosphorylation within the muscle during catch. These experiments, together with *in vitro* observations that paramyosin aggregates underwent a phase transition over a markedly small pH range (6.5–7.2) (Johnson et al. 1959; Ruegg 1961; Ruegg 1964), the extent determined by the degree of phosphorylation (Cooley et al. 1979), have implicated paramyosin phosphorylation in the regulation of the catch state. Because paramyosin smooth thick filaments are thought to have myosin arranged as a surface monolayer (Cohen 1982), it follows that only the outer layer of paramyosin may need to be phosphorylated in order to be functional. Hence, stoichiometries of less than 0.3 moles phosphate per mole paramyosin during catch would be entirely consistent with a putative role for paramyosin phosphorylation during the regulation of catch (Chantler 1983); values in the range 0.1–0.3 moles phosphate per mole paramyosin have been observed (Achazi 1979). Direct functional evidence for this form of regulation is still lacking however. Furthermore, in those instances where paramyosin phosphorylation was deduced from SDS gels, migrating at a position corresponding to paramyosin “aggregates” (Watabe et al. 1989), it is possible that the band observed originated from the recently identified twitchin-related protein (Siegman et al. 1997; Siegman et al. 1998) and may have been mistakenly identified in the earlier work.

As noted above (in Structure of the Smooth Adductor Muscle), a 600 kDa twitchin-like protein exhibited the greatest increase in phosphorylation when ABRM (*Mytilus edulis*) was released from the catch state (Siegman et al. 1997; Siegman et al. 1998). Most importantly, this twitchin-like protein undergoes phosphorylation exclusively during the cAMP dependent release from catch, no phosphate incorporation being detected in paramyosin, myosin light chains or heavy chains, or any other component (Siegman et al. 1998). cDNA sequencing of the N-terminal region of twitchin (from the mussel *Mytilus galloprovincialis*) reveals a putative kinase domain but so far the cAMP-dependent phosphorylation site remains unknown. If the kinase domain is operative, it does not appear to act downstream of cAMP activation because no other component of the muscle appears to be phosphorylated; consequently, it is postulated that phosphorylated twitchin releases the crossbridges from catch (Siegman et al. 1998). Phosphorylated twitchin has no effect at saturating calcium levels but requires some fraction of bridges that are not calcium-activated (Siegman et al. 1998; Butler et al. 1998).

The above results place severe constraints on the role of myosin phosphorylation mechanisms in catch. Nevertheless, one of two myosins found in the smooth adductor muscle of *Patinopecten yessoensis* (Kondo and Morita 1981; Morita and Kondo 1982), in that portion of the muscle furthest away from the striated adductor, is capable of undergoing phosphorylation on its R-LC (Sohma et al. 1985). This was shown using either vertebrate smooth muscle light-chain kinase or an endogenous kinase source (Sohma and Morita 1986; Sohma and Morita 1987; Sohma et al. 1985) and the phosphorylation site on the R-LC was demonstrated to be Ser-11 (Miyanishi et al. 1985). Such a property is more akin to vertebrate smooth muscle regulation than it is to the regulation of scallop striated muscle and raised the possibility that light-chain phosphorylation might play a role in the regulation of catch (Takahashi et al. 1988). Because the latch state of vertebrate smooth muscle correlates with light-chain dephosphorylation (Hai and Murphy 1988) a regulatory role for light-chain phosphorylation would, by analogy, be associated with release from the catch state, similar to the role of twitchin phosphorylation, described above. It may be noted, however, that the actin-activated MgATPase activities (Kendrick-Jones et al. 1970; Perreault-Micale et al. 1996a) of myosins isolated from the smooth adductor muscles of *Placopecten magellanicus* and *Argopecten irradians* are calcium-sensitive and exhibit rates that are independent of R-LC phosphorylation. Consequently, the functional significance of some isoforms of scallop smooth adductor R-LC to undergo reversible phosphorylation may have little relevance for the catch mechanism.

Heavy-chain phosphorylation of ABRM myosin was also observed to occur either in the presence of an endogenous heavy-chain kinase or in the presence of a heavy-chain kinase isolated from the slime mold, *Dictyostelium* (Castellani and Cohen 1987a; Castellani and Cohen 1987b). To date, no direct experiments have been published which would correlate this phosphorylation with specific steps in the catch mechanism. Using shadowed preparations visualised by electron microscopy, these authors were able to show *in vitro* that heavy-chain phosphorylation enhances the ability of the molecule to fold up at low ionic strength (Castellani and Cohen 1987b). These folded molecules are reminiscent of the asymmetric structures seen in the off-state of myosin from the striated adductor muscle (see above). Although they have not been observed *in vivo* as yet, these *in vitro* studies do suggest that events in the neck region of the myosin molecule could be modulated by phosphorylation at the tip of the tail (Castellani et al. 1988). It is plausible that tail phosphorylation could perturb events on the heads of myosin molecules several crossbridge crown repeats removed along the thick filament. Such heavy chain phosphorylation would be associated with release from the catch state (Castellani and Cohen 1987a; Castellani and Cohen 1992).

Catchin, expressed only in molluscan catch muscles, can also be phosphorylated on Ser-103 within its unique N-terminal sequence (Yamada et al. 2000). This was inferred for scallop (*Argopecten irradians*) catchin upon comparison of its sequence with that of a phosphorylated peptide sequence previously isolated from *Mytilus edulis* (Castellani et al. 1988). There is no current evidence for such phosphorylation upon initiation of, or exit from, the catch state. Nevertheless, it has been hypothesised that catchin may act in concert with twitchin during catch, or the unique N-terminus may be involved in tethering

actin while the MHC-derived C-terminal coiled coil could interact with either myosin or paramyosin rod structures (Yamada et al. 2000).

Biochemical (Takahashi et al. 1988) and physiological (Butler et al. 1998; Galler et al. 1999) data have reinforced the emerging view that catch involves a myosin-ADP intermediate locked in an associated state with actin. Force decay in skinned ABRM fibres subject to flash photolysis in the presence of caged-ATP, is slowed approximately five-fold by the presence of MgADP (Galler et al. 1999). Force maintenance during the latch state of mammalian tonic smooth muscles also appears to require a delayed release of MgADP (Fuglsang et al. 1993; Khromov et al. 1995; Khromov et al. 1998). It is plausible, therefore, that cAMP-dependent phosphorylation of twitchin alters the configuration of catch crossbridges such that their affinity for ADP decreases (Butler et al. 1998; Galler et al. 1999). To explain why there was no effect of twitchin phosphorylation on either ATPase or force at saturating calcium levels, Butler and colleagues (1998) proposed that the structures affected by twitchin phosphorylation are those myosin heads that do not possess bound calcium. Their results have been summarised in a semi-quantitative model (Butler et al. 1998) in which the catch mechanism is simulated as a boxed set of reversible first order rate constants relating myosin and actomyosin to their calcium-liganded structures (Fig. 4.23a). Force generation is possible through actin binding but not by myosin alone; catch is represented by actin-bound, calcium-free, myosin. Twitchin phosphorylation is simulated by a 10-fold increase in dissociation rate constant (k_7) and the effects of increasing calcium concentration are simulated through the use of a range of rate constants (k_1) for calcium binding. The predicted tension curve derived from this model, including the relaxing effect of cAMP (Fig. 4.23b), is in good agreement with experimental data (Butler et al. 1998). Even better agreement (the calculated decay curve is exponential whereas the experimental data are biphasic) could be obtained if head-head cooperativity were taken into account and if precise binding data were known for β -actin and catch myosin, both in the presence and absence of calcium.

Many of the key pieces of the catch puzzle are now to hand. Twitchin, a molecule with a structure and periodicities related to both paramyosin and myosin, facilitates the ability of myosin heads to retain MgADP following prior activation (MgATP loading) and calcium dissociation, yet promotes MgADP dissociation upon phosphorylation. The critical differences evident between the primary sequences of smooth and striated adductor muscle MHCs (Fig. 4.11) must somehow facilitate an altered tertiary conformation within the nucleotide binding pocket such that myosin is locked in the actin-associated catch state, a consequence of the increased affinity for MgADP inherent to this conformation. It is likely that such changes must involve switch II (Fig. 4.14). Although the myosin head structure of a catch adductor myosin has not yet been determined, it is clear from other known structures (Dominguez et al. 1998; Houdusse et al. 1999) that entry to, or exit from, the nucleotide binding pocket may be guarded by the E-LC, itself the instigator of the conformational relay which ensues calcium triggering. Determination of the crystal structure of catch muscle myosin heads (or preferably two-headed fragments!) and computer modelling of these within the thick filament structure, paying particular attention to paramyosin, twitchin and catchin packing, should prove a suitable goal for the next decade.

Figure 4.23. Catch simulation using a four-state model. A). MC and M represent detached, non-force producing states of myosin, with and without calcium, respectively. AMC and AM represent force producing states of myosin when attached to actin, with and without calcium, respectively. All rate constants are first order (units of s^{-1}). k_7 is taken to be $0.006 s^{-1}$ when twitchin is not phosphorylated and $0.06 s^{-1}$ when it is phosphorylated. Increases in calcium concentration may be simulated by increasing the value of k_1 . B). Simulated force response curve during a catch protocol (continuous line) in which k_1 was increased from zero ($-Ca^{2+}$) to $1.5 s^{-1}$ ($+Ca^{2+}$) then decreased to zero once again. The effect of cAMP addition was simulated by increasing k_7 from $0.006 s^{-1}$ to $0.06 s^{-1}$ (dashed line beginning at asterisk). This quantitative model for catch, based on earlier consideration of the latch state in vertebrate smooth muscle (Hai and Murphy 1988), was devised by Butler et al. (1998) and is reproduced here with permission of the publishers.

4.7 ACHIEVEMENTS AND GOALS

Many of the earlier predictions (Chantler 1991) have been realised, not only enriching our understanding of the structure and function of scallop muscle but also providing insights into the wider field of contractility. The tools of molecular biology have been used, not only to determine a number of myosin primary sequences from several scallop species (e.g., Nyitrai et al. 1991; Nyitrai et al. 1994; Perreault-Micale et al. 1996b; Janes et al. 2000) but, with ever increasing sophistication, to facilitate the creation of mutant peptides which allow experimental dissection of the regulatory process (e.g., Reinach et al. 1986; Jancso and Szent-Gyorgyi 1994; Yang and Sweeney 1995; Trybus et al. 1997; Wu et al. 1999; Colegrave et al. 2003). Advances in data processing, structural analysis and the art of crystallography have yielded the first detailed structures of scallop myosin heads (Houdusse et al. 1999; Houdusse et al. 2000) and RDs (Xie et al. 1994; Houdusse and Cohen 1996) at atomic resolution. Improvements in sample preparation and image processing have led to advances in large-scale structure determinations of thick filaments and quasi-crystalline arrays by electron microscopic imaging (e.g., Levine 1993; Whittaker et al. 1995; Padron et al. 1997; Wendt et al. 1999). Our knowledge of the intricacies of scallop myosin ATPase kinetics (Kurzawa-Goertz et al. 1998; Nyitrai et al. 2002) and of cooperative aspects of regulation (Walmsley et al. 1990; Kalabokis and Szent-Gyorgyi 1997; Nyitrai et al. 2002; Nyitrai et al. 2003) has expanded. Our understanding of the catch mechanism has advanced dramatically through a series of new and significant findings (e.g., Siegman et al. 1997; Siegman et al. 1998; Butler et al. 1998; Galler et al. 1999; Yamada et al. 2000), though much remains to be learned.

Future goals must include a structural description at the atomic level of the catalytic events during each mechanochemical cycle of scallop myosin heads. With the use of appropriately characterised nucleotide analogs, there is no reason to doubt that this will not be accomplished within the next decade for this approach is already well advanced (Houdusse et al. 2000). Such a proposal might be aided through the defined expression of functional subfragments using appropriate cloning vectors. Myosin heads are too large to be expressed in bacterial expression systems and, so far, baculovirus expression systems have failed to yield functional products using scallop myosin (Nyitrai, unpublished – as quoted in Perreault-Micale et al. 1996b; Janes 2001). Clearly, there is a need to try alternative eukaryotic expression systems. Because complete regulation can only be demonstrated in two-headed molecules, their functional expression or improved production quality (Kalabokis and Szent-Gyorgyi 1997) will be key to any crystallographic attempt to determine the structure of HMM. Herculean as such a task will be, its thunder could be stolen through refinement of other techniques such as computer modelling (e.g., Offer and Knight 1996) or electron microscope imaging techniques (e.g., Wendt et al. 1999) with respect to two-headed scallop myosin fragments. The latter approach may be the most direct way to probe the structure of the inhibited state, another “holy grail” that has so far proven elusive. Potential models can be tested for function using mutant light chains in scallop hybrid myofibrils or myosin (Sellers et al. 1980; Reinach et al. 1986; Goodwin et al. 1990; Colegrave et al. 2003). Alternative ways of achieving inhibition (Patel et al. 2000) may also offer a pragmatic solution to the quest for atomic resolution of the myosin conformation that prevents product release. An understanding of head-head cooperativity (Chantler et al. 1981; Walmsley et al. 1990; Kalabokis and Szent-Gyorgyi 1997; Nyitrai et al. 2002; Nyitrai et al. 2003) at the atomic level is likely to be another major benefit of such structural enterprises, complementing solution studies.

Physiological experiments, in conjunction with the use of specific molecular probes, will continue to be useful in the study of catch contraction. Such approaches could facilitate dissection of the roles of catchin (Yamada et al. 2000), twitchin (Butler et al. 1998) and myosin (Castellani and Cohen 1994) and decipher the meaning of their respective phosphorylation patterns during catch regulation. Physiological studies on the phasic adductor remains the “Achilles heel” of scallop muscle research. Although many pioneering experiments have been performed (e.g., Simmons and Szent-Gyorgyi 1980; Rall 1981; Simmons and Szent-Gyorgyi 1985; Lea et al. 1990), the delicate structure of scallop muscle fibres do not lend themselves to the sort of manipulations required during the demanding studies of crossbridge mechanics. However, we are now in the era of single molecule mechanics. Many elegant experiments have already been performed on various myosin motors through the use of optical tweezers or flexible microneedles (see e.g., Mehta et al. 1999). To date, these techniques have not been applied to components from scallop muscle. Application of laser trap technology to the scallop actomyosin interaction would allow a direct comparison of the step-size and force per head between motors isolated from both tonic and phasic adductor muscles, facilitating correlation between events at the nucleotide binding site and force production. Although the structural similarities between striated and catch adductor myosins are many, it may still

be possible for catch muscle myosin to attain putative increased force simply by generating an increased angle of swing of the lever arm; this would lead to an increased step size and a higher duty ratio (Howard 1997). In principle, single molecule mechanics could determine, once and for all, whether or not there is any intrinsic difference between the force-producing states of striated and catch adductor muscle molecular motors. Another productive decade lies ahead!

ACKNOWLEDGMENTS

I thank the following for providing me with images of published and unpublished material: Drs. Pauline Bennett, Carolyn Cohen, Roger Craig, Arthur Elliott, Clara Franzini-Armstrong, Mike Geeves, Ken Holmes, Daniel Janes, Bob Kensler, Peter Knight, Rhea Levine, Barry Millman, Gerald Offer, Andrew Szent-Gyorgyi and Peter Vibert. I also thank Angie Poole and George Stodulski for help in preparing the figures, and a big thank-you to Sandy Shumway for supporting my request for colour plates. This review was written during the tenure of a grant from the Biotechnology and Biological Sciences Research Council in the U.K.

Chapter 5

Neurobiology and Behaviour of the Scallop

Lon A. Wilkens

5.1 INTRODUCTION

Perhaps the most striking feature of the scallop is the presence of eyes clearly visible around the margin of the shell. This is a somewhat unexpected feature for a bivalve representative of a molluscan class otherwise noted for the reduction of sense organs and cerebral nervous system. An additional 'surprise' is that scallops are able to swim by clapping the valves of the shell in rapid succession. Furthermore, swimming can be elicited by the touch of a starfish in what is now a classic illustration of an adaptive predator-prey interaction. Most of the scallop literature in the area of neurobiology and behaviour is related to vision and swimming, the topics around which this chapter will be centered.

The behavioural repertoire of the scallop, which includes visual responses, and locomotion in conjunction with both escape and migration, is noteworthy among bivalves and corresponds with the free-living mode of existence of this animal. This contrasts sharply with the majority of bivalves either fixed more or less permanently to the substrate by cement or byssal formations, or buried in the substrate. The few additional bivalve species which exhibit overt behaviours, aside from simple siphon retraction and/or valve adduction, are also free living to varying extents. Notable examples include the "swash riding" coquina clam, *Donax* (Ellers 1987), active burrowers such as razor (Schneider 1982) and surf clams which, like cardiids, produce vigorous somersault manoeuvres to escape predation (Feder 1972; Prior et al. 1979), and the flame scallop, *Lima*, which also swims. The giant clam, *Tridacna*, is exceptional in exhibiting various visual and nonvisual behaviours even though sessile in habit (Stasek 1965; Wilkens 1987).

5.2 THE VISUAL SYSTEM

5.2.1 Functional Anatomy of the Eyes

Scallop eyes are located at the tip of a short stalk that extends outward from the middle fold of the mantle lining the circumference of the shell. The blue eyes, 1 to 1.5 mm in diameter, are found in association with both the upper (left) and lower (right) valves, although they occur in greater number and size in the upper mantle (Gutsell 1930). Differences in eye number are especially true of species in which the upper valve is flattened (slightly concave) (Dakin 1909), such as in *Pecten ziczac* where the eyes on the

upper valve can number more than twice those on the lower valve (Wilkins 1981). In a detailed description of the eyes, Dakin (1910a) also points out that eyes vary in number from animal to animal, as well as between species. In *P. opercularis*, for example, he found no correlation between the size of the shell and the number of eyes. In fact, the largest eye count (111) was from one of the smaller scallops in his study. Also, eyes from the upper mantle tend to be slightly larger, and smaller eyes are spaced irregularly among those of full size in both regions (Dakin 1910a).

That there is no set pattern or number of eyes is supported by observations concerning the formation of eyes during development and regeneration. Butcher (1930) concludes that "new eyes . . . make their appearance as space for them is provided". In his experiments on *Pecten* (= *Argopecten*) *gibbus*, eyes regenerated within forty days and their development, beginning as buds along the ophthalmic groove at the base of the tentacles, followed the same course as eyes appearing during growth. To determine the influence of nervous tissue on regeneration, Butcher performed a series of nerve-ganglion ablation and removal experiments and found that none of these procedures had much effect, that is, the eyes regenerated normally. In fact, eyes develop with little difficulty when transplanted at an early stage ("anlagen") onto the epithelial surface of the gonads. Growth of the optic nerve into the gonad also occurs when fully developed eyes are transplanted. It may be that nervous tissue, particularly from the eyes, inhibits the induction of anlagen during normal development, with new eyes forming only as the existing ones separate as the shell enlarges.

The eyes of scallops have attracted the attention of anatomists since the late 18th century primarily due to their resemblance (albeit superficial) to the camera eye of vertebrates (descriptive terms such as iris, rods, and ganglion cells appeared in the older literature reviewed by Dakin 1910a). The essential features of the eye were, in fact, clarified by Dakin and his diagram in sagittal section (Dakin 1910a; redrawn in 1928) has been widely reproduced. The following description is based on this model (Fig. 5.1) with ultrastructural details provided by Barber et al. (1967) (Fig. 5.2).

The functional components of the eye occupy an optic capsule of connective tissue and epithelial cells continuous with the stalk and mantle. Small longitudinal muscle fibres around the stalk allow the eyes to contract from a stimulus but diagonal fibres, present in the constantly moving tentacles, are absent. The epithelial cells are heavily pigmented on the sides of the eye, but distally they form a clear cornea with microvilli at the surface. A lens, comprised of irregular cells with few inclusions, lies beneath the cornea and is bounded laterally by a fluid-filled space.

Lining the back of the eye are the retina, the reflecting argentea and pigment layer. Unlike Dakin's illustration, the retina is not separated by the anterior fluid chamber but, rather, is in direct contact with the lens (*cf.* Figs. 5.2, 5.3A), separated only by a 2 μ m-thick basement membrane. This is an important distinction when considering the optical properties of the eye (see below).

The retina itself is a highly specialised structure, the complexity of which would be puzzling with regard to the visual requirements of sessile bivalves (the thorny oyster *Spondylus* has eyes identical to those of the Pectinidae; Dakin 1928).

Figure 5.1. Diagram of the eye of *Pecten*. [From Bullock and Horridge 1965, after Dakin 1928]

Two distinct layers of retinal cells are present, the primary difference between which is the presence of ciliary versus microvillar sensory regions (supporting glial cells are also present). In the distal layer, each cell gives rise to approximately 100 modified cilia packed in a lamellar array on the distal surface facing the lens and cornea. Axons from these receptors arise lateral to the cilia and, with their fibres passing in front of the retina, collect at the retinal margin on the side of the shell to form the distal branch of the optic nerve. In the proximal layer, the outer segments of the receptors are covered with microvilli facing proximally, and contain one or two cilia with bundles of filaments projecting toward their base. The proximal receptors, with a rhabdom-like interdigitation of closely packed microvilli from adjacent cells, are similar to the photoreceptors of gastropod and cephalopod molluscs (see Barber et al. 1967, for references). The cilia of both proximal and distal receptors have a 9 + 0 fibril arrangement and basal bodies, but lack fibril arms and root systems. Axons from proximal receptors extend around the sides

Figure 5.2. Diagrammatic sagittal section of the eye based on ultrastructural details. Beginning at the outer margin is the cornea (corn.), lens, basement membrane (bm), distal axon, (ax. dist.), distal cell (dist.), proximal axon (ax. prox.), glia, proximal cell (prox.), argentea (arg.), and pigment cell layer (pig.). [From Barber et al. 1967]

of the retina and join at the base of the capsule to form the proximal branch of the optic nerve. Thus, each retinal layer has a separate nerve branch, which extends 1 to 2 mm before joining to form the optic nerve (Hartline 1938b). Further, no synapses have been observed in the retina (Miller 1958; Barber et al. 1967) so that each receptor cell is represented by its own axon in the optic nerve.

The argentea (also tapetum), the reflecting layer responsible for the characteristic bright iridescence of the pupil, lies beneath the retina. This is a single layer of cells containing an array of flattened, membrane-bound guanine crystals and is the biological

Figure 5.3. Diagram of the eye and retinal layers (a) and in relation to the optical system (b). [From Land 1966] (c) Close-up of the eye in *P. maximus* illustrating focused image of a hand. [M.F. Land, unpublished photograph]

equivalent of a multilayered interference mirror (Land 1978). With its precise hemispheric shape, the argentea acts as a concave mirror with a focal length of approximately 200 μm (Land 1965). Thus, an inverted image is formed within the eye and at the level of the distal retina (Fig. 5.3b, c). The focal length of the lens is 1.5 mm and, since it lies in contact with the retina, its image would form behind the eye. The only optical function of the lens may be to correct slightly for aberration in the argentea. Thus, only the distal layer of the retina is capable of reacting to a focused image from a distant object, an important consideration for the physiological properties of the eye.

Finally, a layer of pigmented cells containing EM-dense granules lines the back of the eye.

5.2.2 Retinal Physiology

In view of the anatomic simplicity of the scallop retina, with its separate proximal and distal branches of the optic nerve, Hartline (1938b) believed that this preparation could provide insights into the mechanisms of 'off' discharges like those seen previously in the vertebrate retina (Hartline 1938a). An 'off' discharge in the scallop seemed likely since these animals, like many invertebrates, respond vigorously to shadows — in this case by shell closure.

The physiological mechanisms, which lead to spike discharges in the optic nerves of vertebrates, are actually quite different from those in the scallop. Nevertheless, Hartline (1938b) demonstrated clearly that the two layers of the scallop retina have distinct physiological properties; axons from the proximal layer produce a train of spikes when the eye is illuminated whereas axons from the distal layer respond vigorously when the light is turned off or reduced in intensity. This was established unequivocally by cutting the distal branch of the optic nerve to determine whether or not responses recorded from the common optic nerve had been eliminated (optic fibres are more accessible in the pallial nerves of the scallop; the relevant neural pathways are described briefly in a following section, and in more detail by Beninger and Le Pennec, this volume).

The 'on' response of the proximal retinal cells is typical of invertebrate photoreceptors in that spikes are elicited by light. The 'off' response, on the other hand, is representative of a new and unique type of primary photoreceptor which Hartline (1938b) described as "capable of being stimulated by the removal of an environmental agent." In fact, light itself is inhibitory, a physiological corollary to the activity that ensues at dimming or light offset. For example, re-illumination of the eye during an 'off' response rapidly terminates spiking with a latency of as little as 100 ms, approximately half the minimum latency for burst initiation under optimum conditions (Land 1966). The physiological complexity of 'off' receptor activity is suggested further by the fact that light itself is a prerequisite for the response, with burst strength and rapid onset both dependent on light adaptation (Land 1966). Thus, light has both excitatory and inhibitory effects, with inhibition being more direct in that it overrides the excitatory response. "Primary inhibition," as this phenomenon has been termed (Kennedy 1960), appears to be characteristic of all molluscan 'off' receptors, although the mechanisms may not be uniform. For example, the excitatory and inhibitory components of the 'off' response in *Spisula* are wavelength dependent with inhibition predominant at shorter wavelengths (540 nm) and excitation at longer wavelengths (600 nm) (Kennedy 1960). Whereas this indicates the presence of two photopigments within the same cell, a more recent study on *Mercenaria* (Wiederhold et al. 1973) finds evidence for only a single photopigment. The spectral properties of scallop photoreceptors are considered in the following section.

The functional importance of the 'off' receptors is suggested by the fact that only the distal retina lies in the plane of focus of the argentea. Land (1966) predicted that these receptors alone would respond to movement in the visual field. To test this hypothesis, he stimulated the eyes with a regular pattern of light/dark stripes so that movements produced no net change in overall stimulus intensity. Indeed, when the distal branch of the optic nerve was cut (Fig. 5.4), activity seen previously in response to movement was

Figure 5.4. Abolition of 'off' and movement responses after cutting distal nerve. A photodiode (lower trace) monitors the stimulus: 'on' stimulus (a and d); 'off' stimulus (b and e); moving stripes (c and f), movement signalled by upward deflection. Screen brightness is 500 cd m^{-2} . [From Land 1966]

abolished, even though an 'on' response persisted for control flashes. Tests using a single light or dark stripe produced similar results. A dark stripe, moved stepwise across the visual field triggered bursts of spikes that correspond to the shadowing of previously illuminated distal receptors; light stripes generated no response for similar patterns of movement unless left in one position for 10 s or more, in which case a sufficient level of light adaptation was achieved to trigger an 'off' response when the stripe was moved (Land 1966). The smallest stripe or degree of movement capable of producing a response subtended 2° at the eye, an angle represented by a distance of $9 \mu\text{m}$ in the retina. This approximates the spacing of the retinal photoreceptors.

Although the scallop eye is equipped with two layers of retinal cells, only the distal 'off' receptors are positioned for receiving a focused image. Thus, feature detection in the spatial environment is limited to the distal cell layer, with movement represented by the phasic activity of these photoreceptors. That 'off' cells perform this function is consistent with the fact that in bivalves, 'off' receptors featuring "primary inhibition" serve as shadow detectors (Kennedy 1960; Barber and Land 1967; Mpitsos 1973; Wiederhold et al. 1973). In the scallop, these receptors can signal movements in the environment at distances greater than required to cast a direct shadow on the animal, a distinct advantage for reacting to the approach of a fast moving predator. 'On' receptors, on the other hand, are subject to diffuse light and respond only to changes in overall intensity. The function of these receptors is less well understood although in species (*Argopecten irradians*, for example) where tonic background activity persists in the light (Hartline 1938b;

McReynolds and Gorman 1970a), these receptors could signal absolute levels of light intensity and be useful in migration and habitat selection.

5.2.3 Receptor Potential Biophysics

Scallop photoreceptors, especially the ciliary 'off' receptors of the distal retina, have been featured significantly in comparative studies of visual sensory receptors. Initially, interest in the biophysical properties stemmed from the fact that photoreceptors based on both ciliary and microvillar structures were contained in the same eye. The comparative significance of this unusual dichotomy relates to the evolution of photoreceptor cells and their physiological mechanisms. For example, the photosensitive structures of most invertebrate photoreceptors are composed of microvilli whereas all vertebrate photoreceptors are derived from a ciliary base (Eakin 1965). Furthermore, most invertebrate photoreceptors are depolarised by light whereas those of vertebrates are hyperpolarised. Structure and function, however, are not invariably correlated (Järvilehto 1979).

Intracellular recordings from scallop photoreceptors (Gorman and McReynolds 1969; McReynolds and Gorman 1970a) showed that cells in the proximal layer of the retina ('on' receptors) are depolarised by light and that cells in the distal retina ('off' receptors) are hyperpolarised (Fig. 5.5). Although the receptor potentials in both types are graded, with amplitudes proportional to the logarithm of intensity, depolarising 'on' receptors are at least 2 log units more sensitive to light. Maximum sensitivity in each receptor occurs at a wavelength of 500 nm, which suggests that the same photopigment is used by each cell despite their difference in response polarity. Axonal spikes invading the cell soma are seen occasionally and arise on the depolarising phase of the waveform, that is, at the onset in depolarising and at the offset in hyperpolarising receptor potentials (Fig. 5.6).

Figure 5.5. Responses of depolarising and hyperpolarising cells from the same eye to brief light flashes of varying intensity. Threshold intensity is $\log I = -5.7$ for the depolarising cell (A) and $\log I = -3.0$ for the hyperpolarising (B) cell. The upper trace is the output of a photocell monitoring the light flash. [From McReynolds and Gorman 1970a]

Figure 5.6. Axonal spikes recorded in depolarising (A) and hyperpolarising (B) cells. The duration of the light flash is indicated by horizontal lines. Intensity is $\log I = -4.2$ (A) and $\log I = -2.4$ (B). [From McReynolds and Gorman 1970a]

The receptor potentials in both cells are due to an increase in the ionic current, which crosses the cell membrane (McReynolds and Gorman 1970b). For depolarising receptor potentials, an increase in membrane permeability is consistent with the mechanisms of excitation in other invertebrate photoreceptors. An increase in membrane permeability for hyperpolarising potentials, however, differs from that of vertebrate photoreceptors where hyperpolarisation is due to a decrease in permeability. A detailed analysis of the ionic and spectral properties of the hyperpolarising distal receptors (Gorman and McReynolds 1978; Cornwall and Gorman 1979, 1983a, 1983b) has provided insights into the physiological mechanisms underlying “primary inhibition” in molluscan ‘off’ receptors. In addition, these results add substantially to our understanding of the mechanisms whereby photoisomerisation of visual pigments is coupled to the electrical response.

The hyperpolarising response is primarily a light-activated increase in potassium current (Gorman and McReynolds 1978; Cornwall and Gorman 1983a). The reversal potentials for peak hyperpolarisation bear a Nernstian relationship with external potassium concentrations and attest to the specificity of the response as an outward potassium current. At light offset, repolarisation is due not only to a slow decay in potassium current but also includes a spike-like component (Fig. 5.7A). Various experiments (Cornwall and Gorman 1979) have established that this is a calcium spike and that it is partially obscured in normal circumstances by the residual voltage-dependent potassium current (cf. Fig. 5.7B, where potassium current has been blocked by hyperpolarising current injections). The voltage-dependent calcium current (spike) is also partially inactivated at low membrane potentials due to a sodium leakage current (cf. Fig. 5.7C, 7D). The existence of the calcium spike at light offset acts to increase the rate of repolarisation and may

Figure 5.7. Calcium spike in hyperpolarising photoreceptors. The rapid repolarisation and small overshooting peak are indications of the spike in normal artificial seawater (ASW), (A) and (C). Hyperpolarisation of the membrane ($i = -2.0 \times 10^{-10}$ A) to near the reversal potential for potassium reduces the amplitude of the receptor potential and reveals a spike (B). Replacement of sodium ions with choline (D) also increases the membrane potential and, with the additive effect of depolarising current ($i = -3 \times 10^{-11}$ A), reveals a spike. [From Cornwall and Gorman 1979]

therefore be responsible for triggering the discharge of axonal spikes such as those recorded in earlier studies of optic nerve responses (Hartline 1938b; Land 1966). The calcium spike also provides a mechanism for understanding “primary inhibition” in that relative activation or inactivation of voltage-dependent calcium channels, as influenced by the graded amplitude of the receptor potential and the duration of light-mediated hyperpolarising potassium currents, determines the rate of rise and therefore the burst frequency.

Spectral properties similar to those first described in *Spisula* (Kennedy 1960), are also important considerations for understanding the physiology of ‘off’ receptors. Cornwall and Gorman (1983b) have demonstrated convincingly that shorter (blue) and longer (red) wavelengths, respectively, are responsible for the inhibitory and excitatory components of the receptor potential. These effects can be seen, independent of the ionic currents of the

receptor potential, in the waveform of the early receptor potential (ERP), a small 2–4 mV potential associated directly with a charge shift in the pigment molecules resulting from an intense light flash. Blue light (500 nm) gives a negative ERP whereas red light (575 nm) gives a positive ERP (Fig. 5.8). The negative ERP, it can be concluded (Cornwall and Gorman 1983b), results from the photo-isomerisation of rhodopsin to metarhodopsin and the positive ERP in turn is the result of the regeneration of rhodopsin from metarhodopsin.

Spectral effects of the same polarity are seen in the receptor potential itself. A blue light flash initiates a prolonged hyperpolarising afterpotential (Fig. 5.9) which decays slowly, up to 5 min for an intense flash, and which can be terminated by a red light flash. Similarly, these hyperpolarising and depolarising responses can be attributed to the isomerisation of photopigment to metarhodopsin at short wavelengths, and the regeneration of rhodopsin at long wavelengths of light. Thus, light absorption by different photopigment states triggers opposite long-lasting, light-dependent shifts in membrane potential, both of which are mediated by currents carried through the potassium channels. This is the first demonstration in a photosensory system that light absorption by metarhodopsin directly affects ionic conductance.

Figure 5.8. Effects of wavelength of light on the early receptor potential (ERP). White light, after preadaptation with white light, produces a small depolarisation (middle trace). Maximum responses are produced by red light (positive ERP), after preadaptation with blue light, and by blue light (negative ERP) after preadaptation with red light. Preadaptation with red and blue light, respectively, insures maximum concentrations of rhodopsin and metarhodopsin photopigments prior to the test flash. Response latency is negligible, as indicated by the light monitor (top trace). [From Cornwall and Gorman 1983b]

Figure 5.9. Receptor potential response to monochromatic light. A prolonged hyperpolarising afterpotential is produced by a 3 s blue flash and suppressed by a 200 ms red flash. A burst of small spikes riding the crest of the repolarising response and a prolonged depolarising afterpotential are also produced by the red flash. [From Cornwall and Gorman 1983b]

Cornwall and Gorman (1983b) also reported that shadow responses in the scallop, normally triggered by a decrease in illumination using white light, could be elicited instead by shining red light on two or three eyes when these had been preadapted by blue light. This is a behavioural confirmation of the spectral properties illustrated above (Fig. 5.9). Thus, we have a fairly complete description of the physiological properties of the 'off' receptors in the scallop distal retina, a system uniquely designed to signal behaviourally relevant information (shadows) without the interplay of synapses, as seen in other animals.

5.2.4 Anatomy and Physiology of Vision in the Central Nervous System

In contrast to the eyes, the remainder of the scallop visual system is little understood except for anatomical features of the 'optic lobes'. The relative lack of physiological information reflects the general unfavourability of bivalve ganglia for electrophysiological studies. There are no large cells, as in the gastropod CNS, and an insulating glial constituent is often present.

Visual activity travels to the CNS via the pallial nerves (see Beninger and Le Pennec, this volume), nerves which radiate peripherally from the parietovisceral ganglion to the circumpallial nerve at the margin of the mantle and which contain other sensory interneurons and motor fibres. The optic nerves initially contact the circumpallial nerve, raising the possibility that synaptic interactions occur at this level. However, available evidence suggests that the optic nerves are simply ensheathed in and 'follow' the pallial network into the ganglion. For example, while photoreceptor axons from adjacent eyes converge to a single pallial nerve, in my experience one never encounters activity from a single eye in more than one pallial nerve. Diverging pathways would be expected if synaptic interactions between optic nerve fibres and circumpallial neurons were present. In autoradiographic experiments (unpublished results) in which tritiated proline was

injected into the eye, optic tracts have not been observed to enter the circumpallial nerve despite the intense labelling of optic nerve fibres as they skirt the circumpallial nerve (Fig. 5.10).

The optic fibres terminate primarily in the two lateral ('optic') lobes of the visceroparietal ganglion. Dakin (1910b) clearly established that these crescent-shaped lobes are specialised as visual centres noting that they are present only in scallops and that they vary in size corresponding to the number of eyes present. For example, the left lobe is distinctly smaller than the right lobe in species having fewer eyes in the upper mantle. In *Argopecten*, with its symmetrical valves, the lobes are nearly identical in size. Dakin also correctly interpreted the densely staining glomeruli characteristic of the lateral lobes as being specialised for visual function, and in a diagram has shown fibres from the pallial nerve branching to form one of these spherical structures. Autoradiographic experiments (Spagnolia and Wilkens 1983) have confirmed these observations (Fig. 5.11), and illustrate directly that pallial fibres originating in the eye are associated with the glomerular structures. However, this study suggests that the optic fibres actually terminate in a subcellular neuropile region above (ventral, anatomically) the glomerulus, in which case the glomerulus would consist primarily of fibrillae from neurons originating in the lateral lobe.

Figure 5.10. Darkfield micrograph of a radial section of the mantle showing the base of an eye (injected with tritiated proline), a segment of the optic nerve (o.n.), and a cross section of the circumpallial nerve (c.n.).

Figure 5.11. Autoradiograph of the lateral lobe two days after intraocular injection of labelled precursor. (A) Bright-field and (B) dark-field micrographs of a thionine-stained transverse section illustrate the incoming optic fibres of the radial pallial nerve (RPN), glomerulus (GN), and subcellular neuropile (SCN). Scale bar 100 μ m. [From Spagnolia and Wilkens 1983]

Two or three eyes are located on the anterior- and posterior-most regions of the mantle in association with the wings of the shell (adjacent to the hinge). The pallial nerves innervating these segments of the mantle extend from the cerebral ganglion instead of the parietovisceral ganglion (see Beninger and Le Pennec, this volume). The central connections of the optic nerves from eyes in this region are unknown. Since glomerular

structures have not been described in the cerebral ganglion, it is possible that optic fibres also bypass this ganglion enroute to the visceroparietal ganglion.

Only a brief electrophysiological study of visual activity in the central ganglia of the scallop has been reported (Wilkens and Ache 1977). Attempts to record intracellularly from cells of the lateral lobes have been unsuccessful to date. Thus, our information comes from recordings made at the surface of the lateral lobes by extracellular techniques.

Activity corresponding with both 'on' and 'off' retinal cell layers is present centrally (Fig. 5.12). Although it is not known whether this activity stems from afferent fibres terminating in the lateral lobes, or from neurons of the lateral lobe, there is a consistent difference between the light response recorded in the pallial nerve and the lateral lobe. The 'off' discharge predominant in pallial nerve recordings is relatively weak in the lateral lobe and can be elicited only after light adaptation at high intensities (cf. traces in Fig. 5.12A and B). The 'on' response, on the other hand, is present following either dark or light adaptation, bursts of spikes are distinguishable at stimulus frequencies up to 5–6 Hz, and activity persists with little decrement after the initial burst. These results suggest that afferents from the two retinal layers terminate in different regions of the lateral lobe (tactile-evoked activity in the pallial nerve is also absent in recordings from the lateral lobe, Fig. 5.12C). It is tempting to speculate that the fibres traced autoradiographically to the subcellular neuropile (Spagnolia and Wilkens 1983) are responsible for the 'on' response recorded at the surface of the lateral lobe.

Figure 5.12. Light-evoked neural activity in the lateral lobes (upper traces) and pallial nerves (middle traces) of *Pecten ziczac*; stimulus monitor (lower traces) indicates onset of light with upward deflections. Records begin after 1 min of dark adaptation in (A) and 1 min of light adaptation in (B). The response to tactile stimulation is illustrated in (C). [From Wilkens and Ache 1977]

Both the anatomy and physiology of the lateral lobes indicate a consistent somatotopic organisation of the central visual structures, as might be expected from the arrangement of pallial nerves entering the ganglion. When two or more eyes are labelled autoradiographically, glomeruli in the lateral lobes vary in their position in direct relation to the location of the injected eyes around the shell margin. Similarly, electrical activity recorded from the anterior to posterior regions of the lateral lobes corresponds to stimulation of eyes at the respective anterior to posterior regions of the mantle. Based on the anatomy and physiology of the lateral lobes, it is clear that they are specialised exclusively for visual functions. Motor and nonvisual sensory elements of the pallial nerves form tracts at the base of the lateral lobes which communicate directly with central regions of the ganglion (Stephens 1978; Spagnolia and Wilkens 1983).

5.2.5 Visual Behaviours

Visual behaviours in the scallop include swimming and the orientation of shell position relative to the visual environment, reflex shell closure in response to shadows or movement, and extension of the tentacles toward regions of contrasting light intensity (Buddenbrock and Moller-Racke 1953). The familiar molluscan shadow response, in a strict sense, is probably of less importance for the scallop since image formation in the eye allows detection of movements well in advance of a direct shadow. Accordingly, scallops react more consistently to movement (referred to as the 'sight reaction', as in *Tridacna* by Stasek 1965) than to a general decrease in light intensity, a phenomenon apparent from cursory observations of animals in an aquarium.

The reflexive sight reaction is the most familiar visual behaviour and occurs only in response to decreases in light intensity (Gutsell 1930), or movements involving a dark object. A bright light stimulus will occasionally cause a delayed response (Wenrich 1916), but the circumstances where this occurs are probably not environmentally relevant. In scallops, the opposite behaviour of opening the shell has not been reported for visual stimuli.

The components of the sight reaction include a slight retraction of the mantle velum and valve adduction by activation of the smooth adductor muscle. In recordings of valve movements as well as by direct observation, the visual reflex lacks the twitch-like characteristics of striated adductor-mediated movements. This is confirmed by recording muscle potentials for various responses in the intact animal (Fig. 5.13). For example, the rate of valve adduction for the visual response (A) is lower and clearly distinguishable from the rapid closure triggered by mechanical and/or chemical stimuli (B); the latter type of response is invariably associated with large synchronous muscle potentials (small arrow) from the striated adductor. On occasion, rapid striated muscle contractions contribute to the visual response (see also Fig. 5.14), as reported previously by Land (1968) and Mellon (1969), but experimentally only when fully light adapted; twitch adductions are rarely observed in the field.

Thus, for a visual stimulus shell closure is a relatively 'smooth' response. The degree of closure, onset latency, and duration are variable, as illustrated in Fig. 5.14 by the responses of a scallop stimulated visually by a moving dark stripe. Response latency

Figure 5.13. Adductor muscle EMGs and shell movements in a tethered scallop, *Pecten ziczac*, following visual (A) and mechanical (B) stimuli. EMG electrodes ($7.5\ \mu\text{m}$ Ag wire) were inserted into the smooth adductor muscle. The shadow was produced by an electromagnetic shutter. In (B) the starfish *Coscinasterias tenuaspina* was allowed to contact the mantle and tentacles.

varies from 0.25 s (Fig. 5.13A) to several seconds and valve adduction varies from near complete closure to only a slight decrease in shell gape. Reopening of the shell generally occurs in 5–10 s, although relaxation plateaus may last up to 30 s or more. Prolonged shell closure for several minutes, as occurs following handling, is not characteristic of visual responses.

An additional feature of the sight reaction that is readily apparent is the decrease in sensitivity to repetitive stimulation (Fig. 5.14). For example, a second stimulus within 10–15 s usually elicits no response. For stimulus intervals between 30 s and 5 min, a decrease in response amplitude occurs that is somewhat more rapid for the first few stimuli (6–7 at 2-min intervals) and which appears to be independent of other activities such as the spontaneous ‘cough’ after the sixth trial. Similar results were obtained by Ludel (1974) using a shadow as the stimulus. Summarising her results, the rate of response decrement was greatest for shorter stimulus intervals, as was the tendency for response failures, and neither effect varied as a function of light intensity. It can be concluded, after eliminating the possibilities of receptor adaptation and muscle fatigue, that response decrement is a central mechanism.

To further characterise this effect, that is, to determine whether the response decrement fulfills the criteria for habituation, starfish extract was used as a novel or dishabituating stimulus. As seen in Fig. 5.14, the sight reaction is potentiated after each application of the extract, an effect that was obtained in two of the four animals tested. However, as will be shown in the following section, starfish extract is far less effective as a releaser for escape behaviours than is contact with the intact animal. This suggests that dishabituation could be enhanced by the use of live starfish. Nonetheless, it appears that habituation of the sight reaction, and its dishabituation by the stimulus of a natural predator, is evidence of a simple form of nonassociative learning in the scallop.

Figure 5.14. Visual responses of the bay scallop *Argopecten irradians* to movement of a dark stripe (2.5 cm wide) across the visual field at a distance of 0.5 m. The lower valve was clamped and shell movements were recorded by a force transducer attached to the upper valve. A photocell signalled the stripe as it entered the visual field (arrows). Responses to 18 consecutive stimuli at 2-min intervals are presented. Spontaneous 'coughs' occur after the 6th and 11th stimuli; a brief swim occurred after the 12th. Following the 10th and 15th stimuli a starfish extract was squirted onto the mantle from a syringe (*'s). Valve gape at rest (dashed line) and in response to the stimulus (solid line) is graphed in the insert (lower left) versus trial number. The asterisks indicate valve excursions for the starfish extract-mediated responses. Filled circles indicate spontaneous valve excursions. Net valve adduction is indicated in the graph insert at right.

The protective reflex behaviour is fully consistent with the physiological sensitivities of the distal photoreceptors which respond to dimming and which discriminate movement from a focused image. Thus, sight reactions need not rely on 'off' responses from numerous eyes. Indeed, Buddenbrock and Moller-Racke (1953) report that responses persist when only a single eye is present. In an extensive study of scallop visual

behaviour, these authors also describe a variety of tentacle reflexes and orientation responses. They report, for example, that the long tentacles along a corresponding region of the mantle stretch out toward a slowly moving object. I have also observed tentacles in *P. ziczac* extending toward and 'following' an approaching starfish (within 1–2 cm). Although other sensory modalities could be involved, this behaviour and the related observations by Buddenbrock and Moller-Racke suggest that the eyes function in near-field predator detection. Since escape responses involving chemoreception are invariably dependent on contact with a starfish (avoidance reactions have not been reported for scallops), a visual role for the tentacle response is possible.

Buddenbrock and Moller-Racke (1953) also report that scallops swim in directions influenced by the relative brightness of their surroundings. For example, *P. jacobus*, *P. opercularis*, and *P. flexuosus* swim toward light whereas *P. varius* swims toward dark regions, with orientation possible by shell rotations prior to or during swimming. The proximal receptors are believed to provide the sensory input for these behaviours since activity only from 'on' receptors is suited physiologically for discriminating static visual patterns (Land 1968). Although an image is not formed at the proximal retina, these photoreceptors are nonetheless capable of coarse spatial resolution, being directionally sensitive for the 50° visual field admitted to the eye (Land 1968). The overlap in visual field for the proximal receptors of adjacent eyes would be approximately 80%, an estimate based on 30 eyes arranged radially around the 180° shell circumference (hinge to hinge). Thus, at least 5 eyes would convey information from any point in the visual environment, with intensity weighted relative to the position of each eye and the extent of retinal illumination. Integration of such an overlapping mosaic centrally would provide the information necessary for orientation behaviours. The somatotopic organisation of glomeruli and the 'on' responses recorded in the lateral lobes of the nervous system (Wilkins and Ache 1977), are consistent with this interpretation of visual signal processing and orientation behaviour. However, 'off' receptors in the distal retina presumably would also be active in the case of swimming, especially so in light of the characteristic zig-zag motion of this behaviour.

5.3 THE LOCOMOTORY SYSTEM

5.3.1 Escape Responses and Swimming

In scallops, the methods of escape differ significantly from other bivalves, which either close the shell tightly for long periods of time, or depend on rapid burrowing and/or somersault behaviours utilising the foot. That these strategies are inappropriate is evident considering that the shell valves of the scallop, even when maximally adducted, do not seal tightly at or near the auricles and that the relatively small size of the smooth adductor muscle does not favour prolonged closure against the force of the hinge ligament. Also, the foot is greatly reduced, its use being to lay down byssal threads in some species, or when small in size.

Rather, escape mechanisms (other than the sight reaction described above) are manifestations of quick shell closure and the jet-like propulsion of water from the mantle

cavity. The corresponding structural modifications of the shell, mantle, and adductor muscle are considered to be derived from the adaptations of monomyarian bivalves (Drew 1906; Yonge 1936). Accordingly, changes in shell morphology accompanying the reduction or loss of the anterior adductor, attachment by the byssus — later by cementing, and an open mantle to increase feeding currents are modifications which gave lamellibranchs access to deeper and/or more turbid waters.

With increased turbidity and loss of the siphon, fouling was avoided by the enhancement of ciliary tracts on the palps and ctenidia for sloughing off sediments and a proportionate increase in the striated adductor for rapid valve adduction and currents which transport sediment out of the mantle cavity. In addition, the inner fold of the mantle — the velum or pallial curtain — was enlarged for use in the formation of inhalent and exhalent apertures.

Thus, in bivalves, basic structural modifications necessary for swimming and other escape behaviours are present as a result of changes which accompanied the colonisation of muddy habitats. In the scallop, sediment transported by ciliary tracts inside the mantle collects near the auricles and is ejected laterally and dorsally (Fig. 5.15). This pattern is not only efficient in eliminating sediments and waste, since there is no interference with incurrent streams elsewhere along the shell margin, but it matches the direction of currents used in swimming as well.

Figure 5.15. Currents in the scallop for elimination of sediment and waste materials. Small arrows, ciliary currents on the inner mantle surface, lower valve; bold arrows, currents due to valve adduction. [Redrawn from Yonge 1936; after Kellogg 1915]

Additional features acquired for locomotion include (a) lengthening of the adductor muscle to increase valve gape and the volume of the mantle cavity — and the propulsive force, (b) compression of the hinge ligament into a triangular pad, for maximum velocity of shell opening when the adductor is relaxed, and (c) development of the muscular and sensory components of the mantle which control current direction. The mechanics of escape behaviours, therefore, are centered around currents jetted powerfully from the mantle cavity. The forces are considerable since they must overcome the drag and sinking of a shell that, although lightweight, is neither streamlined nor reduced to the extent found in other swimming molluscs (e.g., cephalopods).

Locomotion was first studied systematically by Buddenbrock (1911) and comprises three basic manoeuvres (Fig. 5.16), die Schwimmbewegungen (swimming), die Fluctbewegung (an escape or “jump” response; Thomas and Gruffydd 1971), and die Umkehrbewegung (the righting reflex); locomotory jet currents also are used by some species for excavation or burying activities. In swimming, water is taken into the mantle cavity ventrally and laterally during valve abduction and exits dorsally near the shell auricles during adduction to generate thrust for forward movement. Longitudinal muscles in the velum stiffen during adduction to prevent the forward escape of water, although some escape ventrally through the overhang of the upper mantle is thought to produce an upward force at the leading edge of the shell (Buddenbrock 1911). The dorsal jets produce an explosion of sand at the onset of swimming whereas little or no substrate disturbance is apparent elsewhere suggesting that the volume is proportionately small for the upward force. Hydrodynamic factors undoubtedly are involved in swimming as well, and these will vary somewhat depending on the shape of the shell (Stanley 1970). For example, the valves in *Placopecten* and *Amusium* are much less convex than in other scallops and these genera are among the most adept swimmers. The upper valve in *Placopecten* in fact is slightly more convex than the lower valve and may act as a hydrofoil in providing lift, a prediction correlated with the horizontal plane of the commissure during swimming in this genus (Stanley 1970). In scallops where the biconvex valves are equal, or nearly so, or where the upper valve is slightly concave (planoconvex), lift is predicted only when the plane of commissure is inclined during swimming, as it is in most species. However, from tests in flowing water (Gruffydd 1976), only *P. maximus* (planoconvex) produced lift when held with the shell commissure horizontal whereas *Placopecten*, *Chlamys islandica*, and *C. opercularis* required that the shell commissure be inclined. Lift, whether due to the inclination of the shell or to downward-directed currents, is not haphazard. Various reports indicate that swims of any distance begin with a steep climb after which movement is horizontal (Olsen 1955; Bourne 1964; Stanley 1970; Morton 1980). Swimming directed toward a visual pattern (Buddenbrock and Moller-Racke 1953) or away from a predator (Winter and Hamilton 1985) also suggests that currents jetted from the mantle are actively controlled by the velum.

For jump and righting behaviours, water is taken into the mantle cavity as in swimming. During the jump response, however, water is jetted back out of the ventral margin. Unlike the swim, in which the scallop appears to take successive bites out of the water (Dakin 1909), escape jumps characteristically involve 1–3 valve closures.

Figure 5.16. Jet-like currents involved in locomotion by the scallop. (A, B) Top and side view of swimming currents. (C) Currents used in jump responses. (D) Currents used in the righting reflex. Broken arrows indicate direction of current; solid arrows the direction of movement. (T) represents turning. [Yonge 1936; after Buddenbrock 1911]

Nonetheless, several behavioural responses are possible depending on the extent or strength of valve adduction and the direction of the jet current. For example, water jetted ventrally causes backward movement (hingeward), whereas water jetted laterally will result in movement in an anterior or posterior direction. In some instances water is jetted dorsally, as during swimming, but from only one side to effect a rotation of the shell. Alternatively, in planoconvex scallops recessed in the substrate, jump-like adductions do not result in movement of the scallop but instead dislodge, or possibly startle, potential predators.

Shell movements associated with locomotory and escape behaviours have been recorded by mechanoelectric devices attached to the upper valve, with the lower valve fixed to the chamber floor (Thomas and Gruffydd 1971; Stephens and Boyle 1978), or indirectly by monitoring the pressure in the mantle cavity (Moore and Trueman 1971).

Valve movements also have been recorded in tethered scallops (Wilkins 1981), a situation where the freely-moving animal is less likely to be influenced by the recording apparatus, particularly with regard to the dynamic forces associated with swimming (Vogel 1985). Various shell movements characteristic of the Bermuda sand scallop *P. ziczac* are illustrated in Figure 5.17. The resting position of the valves, as seen for these spontaneous behaviours, is characteristically about half the maximum shell gape, although some scallops may gape more widely. Coughs associated with irrigation of the mantle cavity are generally regular (see also Stephens and Boyle 1978), occurring singly (A) or in bouts (B); irregular activity may occur also, such as under crowded conditions in an aquarium (C), or after handling (Thomas and Gruffydd 1971). Invariably, each cough is preceded by an increase in shell gape, thereby increasing the volume of the mantle cavity. Likewise, increases in shell gape precede escape closures, a further indication of the relationship between cleansing mechanisms and swimming.

In coughs, jumps, and swims, valve adduction is rapid due to activation of the fast adductor (cf. Fig. 5.13). In contrast, the valves reopen gradually, except during swimming as seen more clearly at a faster time base (Fig. 5.17C). Thus, both fast and slow components of the adductor muscle are activated during these behaviours, slow relaxation of the smooth adductor being responsible for the gradual reopening of the shell. In swimming, activation of the smooth muscle is delayed until the end of the swim episode. Of equal importance to the twitch-like valve adductions, the shell must be able to reopen quickly during swimming, a requirement for the repetitive valve adductions (at 2–3 Hz) necessary for the scallop to remain waterborne. The primary opening force is supplied by the elasticity of the hinge ligament. However, Vogel (1985) has estimated that at a

Figure 5.17. Spontaneous valve movements in *Pecten ziczac*. Records are from tethered animals partially recessed in the sand. Upward traces represent valve adduction. [From Wilkins 1981]

swimming velocity of 0.5 m s^{-1} , in *A. irradians* a force approximately one-quarter that of the hinge ligament is generated by movement of the shell through the water. In effect, an increase in internal pressure from the force of water at the ventral gape, and a decrease in outside pressure from water flowing over the convex surfaces of the shell, combines to assist the hinge in rapid valve abduction.

Scallops utilise their locomotory abilities primarily to escape predation and for habitat selection. Evidence of starfish-mediated swimming goes back at least to Dakin (1910b) who noted that the "close proximity" of *Asterias rubens* is the only stimulus effective in inducing swimming in *P. opercularis*. Indeed, a variety of predatory starfish and gastropods are reported to elicit swimming and/or jump escape responses when contact is made with the scallop mantle (Buddenbrock 1911; Lecomte 1952; Olsen 1955; Mellon 1969; Moore and Trueman 1971; Thomas and Gruffydd 1971; Bloom 1975; Stephens and Boyle 1978; Forester 1979; Ordzie and Garofalo 1980; Wilkens 1981; Peterson et al. 1982; McClintock 1983; Chernoff 1987; Pitcher and Butler 1987); translocations up to 3 m have been measured in the field for *A. irradians* (McClintock 1983), 4 m for *P. magellanicus* (Caddy 1968), and exceeding 10 m in *A. pleuronectes* under experimental conditions (Morton 1980). Were it not for these 'violent' reactions, which affect successful escapes by the scallop in many instances, predation levels would certainly be greater. As it is, laboratory estimates of successful attacks on *A. irradians* by the oyster drill *Urosalpinx cinerea* are high (72.3%), with a mean density of attacks in the field of 1.7 m^{-2} . An estimated 75–80% destruction of Tasmanian scallop beds (Olsen 1955) and a mortality rate up to 25% for *P. magellanicus* in the Gulf of Saint Lawrence (Dickie and Medcof 1963) are effects attributed primarily to starfish predation. Escape locomotion is also thought to reduce predation in gastropod molluscs (Feder 1963; Margolin 1964).

In addition to locomotion, scallops (principally *Chlamys* sp.) derive protection from the encrustment of sponges on the upper valves (Bloom 1975; Chernoff 1987; Pitcher and Butler 1987). This mutualistic association is synergistic with the behavioural responses, increasing the probability of escape due to the interference of adhesion by starfish tube feet. Similarly, shell coloration, with the dorsal valve typically darker, and encrustment by benthic invertebrates other than sponges may offer protective camouflage.

Substrate and habitat characteristics are also major factors, which influence locomotory behaviour in scallops. Planoconvex scallops, *P. maximus* for example, which are normally recessed in sandy or sand-mud substrates swim frequently and disperse widely when placed on hard substrates (Baird 1958); when placed in sand little or no swimming occurs. An increase in swim frequency associated with hard substrates, and a greater tendency for small or unrecessed animals to swim has been noted for *P. maximus* by other investigators (Hartnoll 1967; Baird and Gibson 1956; Gruffydd 1976, for smaller *Chlamys*). Perhaps related to the life habits of 'recessing' scallops, visual stimuli or other disturbances generally do not induce swimming. For example, *P. maximus* reportedly does not swim in response to visual stimulation (Land 1968), the approach of divers (Baird 1958), or dragging operations (Baird and Gibson 1956); visual and tactile stimuli (except for starfish) are also ineffective for *P. opercularis* and *P. jacobus* (Dakin 1910b). *A. pleuronectes* can be induced to swim only when picked up and drained of water (Morton 1980). Conversely, Caddy (1968) reports that *Placopecten* first faces away and

then swims at the approach of a diver and that swimming accounts for a low drag capture efficiency (2.1%). However, large animals (>100 mm) again show a marked decrease in the tendency to swim.

Habitat preference is reversed for the bay scallop; *Argopecten* normally inhabits seagrass beds as opposed to sandy substrates. Experimentally, the probability of swimming is significantly greater when scallops are placed in a sandy area, and the distance covered by swimming increases for larger diameter sandy test sites (Winter and Hamilton 1985). Camouflage, food resources, and interference with the movements of predators are among the possible advantages afforded by seagrass beds.

Although it is not clear whether scallops routinely migrate long distances, circumstantial evidence suggests that swimming is used by some species for migration and that, in relation to swimming, community structure is further influenced by currents. For example, Morton (1980) argues that swimming in *Amusium* is sufficiently well developed as to make it "extremely doubtful that [it] is used merely for escape." The seasonal appearances of *Amusium* sp., based on the coastal scallop fisheries of Hong Kong, are also cited in support of mass migrations by this species. Yonge (1936) also states that *C. opercularis* and the bay scallop *A. irradians* make extensive migrations, a claim often made by fishermen and supported by my own collecting experience in the northern Gulf of Mexico (pers. obs.). Moore and Marshall (1967) also note that displacements of *Argopecten* are related to tidal currents. In *C. islandica*, the propensity to swim is augmented by current (Gruffydd 1976), a factor which may affect their distribution. For example, older scallops are found in the innermost regions of Norwegian fjords where inward-flowing currents are stronger than those flowing outward. Olsen (1955) also reports that adult scallops in the waters of Tasmania are consistently found in highest concentrations where tidal currents are strong and in beds parallel to the direction of flow, even though no differences in bottom characteristics were discernible. It is not surprising that swimming is effected by currents since the efficiency of directed locomotion would increase or decrease with current direction, and additional movement would continue after the swim as the scallop settles passively to the substrate.

5.3.2 Sensory and Motor Functions of the Mantle

The ciliated epithelial cells of the mantle, particularly those on the tentacles, serve as the primary sensory receptors for tactile and chemical stimuli. Two probable sensory structures of uncertain function, the abdominal sense organ and a structure reminiscent of the gastropod osphradium (Beninger and Le Pennec, this volume), are located inside the shell but the mantle edge is clearly preferable for most sensory features, as indicated further by the presence of the eyes.

The mantle tentacles have been associated primarily with the detection of predators but they undoubtedly contribute to a variety of activities. In fact, tentacles of different size and location are present; long tentacles which arise from the middle fold of the mantle in line with the eyes, and short tentacles on both the middle fold lateral to the eyes and lining the front edge of the velar curtain (inner mantle fold). There is no evidence, physiological or otherwise, that differences in sensitivity exist between the two types.

However, the short interlocking tentacles of the velum would seem appropriate for excluding unwanted particulate matter from the incurrent streams and may be sensitive primarily to tactile stimuli. The activity of the long tentacles suggests that they are involved in detecting either the suitability of the substrate or the posture of the shell in relation to it, or both. In *Argopecten*, for example, the long tentacles of the lower mantle typically extend downward, often in contact with the substrate. In the sand scallop *P. ziczac*, the lower tentacles curve tightly around the margin of the lower valve when the shell rests on the sand instead of extending outward as when recessed. The long tentacles therefore act as if they monitor substrate texture and shell position, but the chemical essence of the substrate also may be detected by this activity.

Chemosensitivity in the scallop is understood essentially from behavioural assays, that is, escape responses. Both swim and jump reflex behaviours are dependent on specific chemical releasing factors found in their predatory coinhabitants. In all instances, these responses appear to be contact dependent, an indication that the chemical stimulant is not released by the starfish or snail and/or that both tactile and chemical stimulus components are required to trigger an escape response. Peterson et al. (1982) also have shown that scallop emigration is significantly higher from test quadrants containing the predatory snail *Busycon* even though whether the scallops having fled actually came into contact with the snail was not determined. Scallops also discriminate between predatory and nonpredatory species. In *A. irradians*, the predatory *Asterias forbesi* and *Luidia clathrata* evoke swimming whereas the nonpredatory *Echinaster* sp. and *Henrica sanguinolenta* do not (Stephens 1978; McClintock 1983; Winter and Hamilton 1985). Predatory snails (*Urosalpinx cinerea*, *Eupleura caudata*, *Thais lapillus*, *B. canaliculatum*) are also distinguished from nonpredators (*Littorina littorea*, *Ilyanassa obsoleta*), as indicated by longer swims and shorter response latencies in the former group (Ordzie and Garofalo 1980). In *P. maximus* the predatory starfish *A. rubens*, *Marthasterias glacialis*, and *Astropecten irregularis* evoke swimming but the nonpredatory *Porania pulvillus* and *H. sanguinolenta* do not (Thomas and Gruffydd 1976). *P. jacobaeus* also distinguishes behaviourally between different asteroid species (Dakin 1910b; Lecomte 1952).

Active components isolated from the surface exudates of starfish extracts (*M. glacialis*) trigger escape responses like those evoked by the intact starfish (Mackie et al. 1968; Mackie 1970). These compounds have been identified as steroid glycosides (M1 and M2) and, like the synthetic surfactants Triton X-100 and Tergitol NPX, are effective escape stimulants for a variety of benthic invertebrates including the snail *Buccinum* and the brittle star *Ophiothrix*. In *P. maximus* and *C. opercularis*, threshold concentrations of starfish steroid glycosides cause tentacle withdrawal and contractions of the velum. Swimming is induced at higher concentrations (Mackie 1970; Stephens and Boyle 1978) but the frequency of swim responses was not addressed in these experiments. As observed by Thomas and Gruffydd (1971), and in my experience (Wilkins 1981), the pipetting of solutions of starfish extract onto the mantle is much less effective as a stimulus for swimming than direct contact with a live starfish.

The stimulus-response characteristics of the starfish-scallop interaction are highly stereotyped as well as species specific. Most stimuli, including those triggering the sight reaction, result in closure of the shell with valve adductions ranging from partial to

complete; duration of shell closure generally reflects the intensity of stimulation. For example, any moving object large enough to cast a shadow or to create a near-field disturbance to which the animal is unaccustomed will cause the shell to close briefly. Direct probing of the mantle with any of a variety of glass, wood, or metallic objects generally causes rapid and sustained closure, sometimes followed by a delayed swim (Dakin 1910b; Thomas and Gruffydd 1971; Stephens and Boyle 1978; Wilkens 1981). However, contact with a predatory starfish invariably causes the shell to open widely, a response quite distinct from that of any other tactile stimulus. The behaviours described above are illustrated in Fig. 5.18. In each of these trials the scallop closed its shell when the starfish was introduced (by hand) into the aquarium. Even when completely adducted, as in 4 of the 6 trials shown here, contact by the starfish with only a few retracted tentacles produced an immediate (in a matter of seconds) opening of the valves, the biological equivalent of using a key to open a lock. A swim or jump response follows if the starfish remains in contact, generally for 5–10 s. In related experiments, responses were obtained by probing the mantle with a bare stainless steel wire and by a single tube foot into which the wire had been inserted (Wilkens 1981).

Again, the wire probe triggered shell closure whereas the tube foot caused shell opening and an escape response. Subsequent tests with *A. irradians*, *A. gibbus*, and *Notovola meridionalis* have produced similar results (unpublished observations). These results highlight the sensitivity as well as the combined chemo-tactile specificity of receptors in the scallop mantle to the stimulus of a natural predator. Scallops also differ somewhat in their responsiveness to starfish. Indeed, swimming is energetically expensive and Thompson et al. (1980) report that following a swim, *P. magellanicus* becomes refractory to further stimulation by starfish extract for 1–3 hr. *P. ziczac* will swim repetitively (Fig. 5.18) but the number of valve claps per swim decreases and the response latency may increase for successive swims.

The underlying sensory as well as motor organisation of the mantle, as it relates to various behaviours, has been described by Stephens (1978) and Stephens and Boyle (1978). With the mantle isolated from the central nervous system the tentacles become elongate and immobile and spontaneous activity in the afferents of the pallial nerves is absent. However, mechanical stimulation of a tentacle will cause it to retract and a broader stimulus will produce a localised retraction of the mantle edge, events associated respectively with single and multi-unit bursts of spikes in adjoining pallial nerves. Starfish extracts applied to the mantle also produce local retractions and are characterised by an initial multi-unit burst of activity followed by a low level afferent discharge for 30 s or more (Stephens 1978). If synaptic mechanisms are blocked by soaking in calcium-free, high-magnesium solutions, reflex movements and pallial nerve activity reversibly disappear. Thus, local reflex responses of the mantle, including those that resemble jet formation in the intact animal, are coordinated peripherally by synaptic interactions in the circumpallial nerve. These results also indicate that afferent activity in the pallial nerves, except for that in the optic nerves, is not from primary mechano- and chemoreceptors. Whether sensory blockade is peripheral to or at the level of the circumpallial nerve is unknown.

Figure 5.18. Starfish-mediated escape responses in *P. ziczac*. Valve movements are from an unrestrained scallop in response to contact by the starfish *Coscinasterias tenuaspina*. Consecutive stimuli were presented at 2-min intervals along the ventral edge (left-hand column), or at the posterior auricle (right-hand column) of the shell. These responses are characteristic of a sequence of 18 consecutive trials. Arrows indicate stimulus onset; adduction is represented by upward deflections. Calibration, 1 min. [Adapted from Wilkens 1981].

Jet apertures are formed by retraction of the radial muscles in corresponding regions of the upper and lower mantle velum, as illustrated in *P. ziczac* (Fig. 5.19). That jets are formed at the point of contact by the starfish is important for the escape jump in that currents are aimed directly at the predator. In an unrecessed scallop, *C. opercularis* for example, the resultant escape movement is in a direction opposite the point of attack (Stephens and Boyle 1978). For a recessed scallop the force of the current drives back the starfish. A similar directional, exhalant current is used by the giant clam *Tridacna* to startle and/or drive away potential predators (Stasek 1965).

The physiological mechanisms associated with jet formation and related behavioural responses can be investigated by direct activation of sensory tracts in the pallial nerves. These nerves are readily accessible after the careful removal of one of the valves. Weak en passant stimulation of a pallial nerve on one side of the animal (Fig. 5.20A) produces a threshold response in the corresponding contralateral nerve (Stephens 1978). This unilateral response is resistant to fatigue and calcium-free saline suggesting that reflex contractions of the type which form jets are coordinated by neural pathways involving electrical synapses which cross the visceroparietal ganglion to sites opposite in the mantle. Cobalt backfillings of pallial nerves also stain tracts through the ganglion and into the appropriate pallial nerves on the opposite side. Higher intensity stimulus pulses trigger a more sustained response in the corresponding nerves of both sides (Fig. 5.20B). This activity is correlated with rapid infolding of the velar curtain and is sensitive (reversibly)

Figure 5.19. Jet formation (arrow) in *Pecten ziczac* at the point of contact by a ray and tube feet of *Coscinasterias tenuispina*. Note also the outstretching of tentacles toward the starfish.

to calcium-free saline and fatigue. With further increases in stimulus intensity, the smooth and then striated adductor muscles are activated (Fig. 5.20C, D); stimulus trains evoke swim-like rhythmic sequences of activity in the pallial nerves and striated muscle (Fig. 20E).

These results demonstrate at least a rough correlation between the stimulus intensity, as might range from lightly touching the mantle or tentacles to sustained contact by a predatory starfish, and neural responses, which correspond with jet formation, an escape jump, and a swim. The infolding of the velum, described as a protective response (Stephens 1978), represents the contractions of longitudinal muscles, which stiffen the velum and thus prevent water from escaping the mantle cavity other than at sites of jet formation. I have recorded equivalent ensembles of neural activity from the completely isolated ganglion of *Argopecten* (unpublished results) in response to a similar sequence of pallial nerve stimuli. An additional stage in the level of ganglionic excitation involves activity triggered in the ctenidial nerve. This response precedes activation of the striated muscle efferents and corresponds with an anterior retraction of the gill axis in anticipation of a jump or swim.

5.3.3 Innervation and Neuromuscular Physiology of the Adductor Muscle

As noted above, the adductor muscle of scallops and other monomyarianans is composed of two distinct types of muscle (Yonge 1936), a fast, twitch-like block of striated, somewhat translucent fibres and a slow, smooth muscle component of smaller, opaque fibres. In scallops the striated muscle constitutes 70–80% of the adductor mass.

Figure 5.20. Efferent responses and mechanograms (a) from stimulation of the pallial nerves. (A) Threshold pulse evokes short-latency burst in the contralateral pallial nerve (rc); (B) Higher intensity pulse evokes a threshold response (arrow) followed by synchronous bursts on both sides. (C) Synchronous burst in pallial nerve and slow adductor contraction. (D) High stimulus intensity pulse triggers burst in pallial nerve and a fast muscle contraction (s, myograms in C and D). (E) Trains produce multiple cycles of activity. Calibration: 100 μ V; 50 ms, A, B; 100 ms C-E. [Adapted from Stephens 1978]

The position of the adductor muscle in relation to the shell and nervous system is illustrated elsewhere in this volume (see Beninger and Le Pennec). The visceroparietal ganglion (VPG) lies on the anterior surface of the adductor and hence on the striated portion of the muscle.

Innervation of the smooth and striated muscle components by nerves from the VPG is equally distinct. A pair of bilaterally symmetrical nerves to the smooth muscle extend ventrally from beneath the VPG, course over the surface of the striated muscle and inward at the juncture of the two muscle blocks. The motor nerves innervating the striated muscle also emerge from the surface of the ganglion facing the muscle and branch, on each side, into three primary trunks – anterior, lateral, and posterior. Each trunk extends only a short distance before additional branches form and penetrate the striated muscle mass (unpublished results from *A. irradians*).

Despite the fact that the smooth muscle can be readily isolated with its efferent nerve supply intact, the efferent mechanisms which control this muscle are poorly understood. Stimulation of either the nerve or muscle produces contractions which decay slowly (5–10 s for return to baseline) and therefore summate readily into sustained contractions (Wilkens 1981). In contrast, the pattern of innervation and the junctional physiology of

muscle fibres in the striated adductor is relatively well understood (Mellon 1968). By focal stimulation of small nerve branches and intracellular recording from single muscle fibres, a multiterminal pattern of muscle fibre innervation has been shown to exist. This is illustrated by a stepwise series of excitatory junction potentials (EJPs) whose amplitudes correspond reproducibly with stimulus thresholds for individual motor neurons (Fig. 5.21A). It was also shown that adjacent muscle fibres, and presumably muscle fibres within a motor field, are innervated in common by branches of the same motor neurons (Fig. 5.21B).

Muscle spikes arise from the EJPs, but typically only in response to more intense electrical stimulation and the temporal summation of junction potentials. Both overshooting (Fig. 5.21C) and undershooting spikes are seen although some fibres fail to spike. Thus it seems that spike threshold is high and/or that regenerative activity may be restricted to certain portions of the muscle fibre.

Graded contractions of the striated adductor may be possible as a result of high spike threshold and multiterminal innervation, although as yet no simultaneous recordings of mechanical tension have been obtained to test this hypothesis. For example, either spatial or temporal recruitment of EJPs could produce graded contractions, a mechanism similar to that of the multiply-innervated muscles in arthropods, as long as the spike threshold was not exceeded. In the intact animal the strength of contraction in the striated muscle varies, as indicated by rapid adductions ranging in extent from those of coughs to complete shell closure during swimming. Unlike arthropods, however, no inhibitory junction potentials have been observed, and the EJPs are non-facilitating and resistant to fatigue at stimulus frequencies up to 10–20 Hz, well above the rates necessary for swimming.

Figure 5.21. Junction potentials in striated muscle fibres. (A) Superimposed responses from a single fibre to stimuli of increasing intensity. (B) Similar response patterns from adjacent muscle fibres show common thresholds to nerve stimulation. (C) Summation of junction potentials with an over-shooting spike superimposed on the response at highest stimulus intensity. Calibration: (A, B) 20 mV, 20 ms; (C) 25 mV, 50 ms. [Adapted from Mellon 1968]

A striking feature of the motor system innervating the striated muscle is the close synchronisation of EJPs, a requirement for achieving maximum strength of contraction. Electromyograms (EMGs) recorded from the striated muscle of *A. irradians* during swimming characteristically show a single muscle spike for each adduction of the valves (Mellon 1969; Stephens and Boyle 1978), and the time course of the extracellularly recorded spike is comparable to that of the muscle action potential recorded intracellularly (Mellon 1968). There is also close synchronisation of the EMGs in different motor fields, including activity which originates from nerves on both sides of the ganglion. Thus, Mellon (1969) suggests that striated muscle motoneurons in the VPG may be electrically coupled; pools of electrically coupled motor neurons are well known from other animals. In other evidence, contractions in the striated muscle can be triggered by stimulating (antidromically) the cut proximal stumps of the lateral or posterior nerve trunks (unpublished results) if the anterior branch remains intact. These results are evidence for the electrical coupling of motor neurons although it is possible also that branches of the same motor neurons are found in each nerve trunk.

An interesting and as yet poorly understood feature of the scallop adductor concerns the regulation of tension in the smooth muscle. In the undisturbed animal, shell gape is maintained at or slightly greater than half maximum during normal feeding. Cutting the smooth adductor allows the valves to open widely whereas disruption of the striated muscle, in part due to trauma, results in partial smooth muscle contractures and smaller valve gapes (Mellon 1969; Stephens 1978; Wilkens 1981). Thus, the smooth muscle clearly exerts continual tension in opposing the opening force of the hinge resilium. The wide gaping of the valves triggered by a starfish or in advance of spontaneous cough and swimming behaviours is due therefore to relaxation of the smooth muscle.

It is unclear whether long-term tension in the smooth adductor depends on tonic excitatory input from the VPG or whether the muscle exists normally in a state of partial 'catch' tension. Lowy (1954) favours the tonic hypothesis, with relaxation resulting from a decrease in efferent activity. However, in electrical recordings from the nerve, and directly from the smooth muscle, tonic discharges consistent with activity that would be required for sustained tension have not been observed (Wilkens 1981). On the contrary, efferent discharges arise which correspond with muscle relaxation and increased valve gape (e.g., Fig. 5.13B). It is of interest, further, that contractions of the smooth muscle produced by ongoing electrical stimulation of the muscle itself can be effectively reversed by a starfish stimulus (Fig. 5.22). Thus, it seems certain that an active mechanism is responsible for relaxation of tension in the smooth adductor muscle and the corresponding valve abductions seen in various behaviours. Curiously, relaxation cannot be induced by electrical stimulation of the smooth muscle nerves in either the intact animal or in the isolated nerve-muscle preparation; electrical stimuli produce only muscle contractions.

5.3.4 Coordination of Locomotory Behaviour by the Central Nervous System

As previously described, swimming, escape, and visual behaviours are brought about by activity in the mantle and adductor muscle effectors. Local reflexes in the mantle are coordinated in part by the circumpallial nerve, in effect a circular ganglion, and by the

Figure 5.22. Tetanus-like contractions of the smooth adductor muscle evoked by direct electrical stimulation through electrodes implanted in the muscle. A starfish stimulus (arrows) triggers muscle relaxation as well as jumps (top record) and a swim (middle record); insets at right illustrate the site of contact by the starfish. Stimulus parameters: train rate, 0.5 Hz; train duration, 250 ms; pulses, 1.5 V and 1 ms. [Adapted from Wilkens 1981]

VPG by way of afferent and efferent tracts in the radiating pallial nerves. The adductor muscle is innervated entirely by efferent nerves from the VPG. Thus both sensory and motor functions of the scallop are dominated by the VPG, the largest of the central ganglia and most complex within bivalve molluscs (Dakin 1910b). However, not all pallial nerves connect centrally with the VPG; those which innervate dorsal segments of the mantle at the shell auricles originate from the cerebral ganglion instead.

Less is known about the role of the cerebral ganglion in the behaviour of scallops than is the case in other bivalves (reviewed by Bullock 1965) where cerebral functions include reflex control of the anterior adductor, coordination of visceral and pedal activities, and a dominant influence on behavioural rhythms. Nevertheless, several observations attest as well to the dominance of cerebral function in the scallop. Specifically, the cerebral ganglia are instrumental in behavioural decision making with respect to swimming or other escape responses and contain integral components of the neural circuits for these behaviours. For instance, a starfish stimulus along regions of the mantle innervated by pallial nerves from the cerebral ganglion triggers a significantly greater number of swim responses than equivalent stimulation at any other site; elsewhere an escape jump ensues (Wilkens 1981). This behavioural dichotomy is illustrated in Fig. 5.18 in data excerpted from a longer sequence of jump and swim responses. Equivalent results have been observed in *A. irradians* (unpub. obs.) and responses triggered by stimulation of the dorsal mantle, in this case by a predatory gastropod, also have a

significantly shorter latency than equivalent stimuli along the ventral margin of the shell (Ordzie and Garofalo 1980). Thus, what otherwise may be equivalent sensory information, but from different regions of the mantle, triggers different behaviours depending on whether the information enters the cerebral or visceroparietal ganglion. Since jet formation is not possible along the hinge, or where the mantle is fused at the shell auricles, a swim is the appropriate response if a predator is detected at the dorsal shell margin. Whether or not susceptibility to predation is greater for attacks at the dorsal edge of the shell has not been determined.

The correlation between swimming and sensory input to the cerebral ganglion suggests that these ganglia are necessary for the initiation of swimming behaviour. Indeed, swimming does not appear to be possible if the cerebrovisceral connectives (CVCs) are cut (Stephens 1978; Wilkens 1981). Cutting the CVCs not only interrupts descending pathways otherwise activated by the dorsal mantle but also eliminates a component of the swim neural circuit in the cerebral ganglion since, under these circumstances, responses triggered from ventral regions of the mantle affect only weak jump-like valve adductions. It can be concluded that the occasional swims that result from stimulation of ventral mantle under experimental conditions, or at lower stimulus threshold in undisturbed animals, involve neural elements in the cerebral ganglia brought into play by activity in ascending pathways of the connectives. The circumpallial nerves do not substitute for or constitute pathways parallel to those in the connectives, as is evident from the behavioural disruption which follows transection of the CVCs. A functional pallial-circumpallial-pallial circuit between the cerebral and VPG is also unlikely in that the spread of electrical excitation decrements rapidly in the circumpallial nerve, as seen in experiments with the isolated mantle (unpublished results).

Isolation of the cerebral ganglia also profoundly alters the 'resting' posture of the animal by interfering with the ability of the smooth adductor muscle to relax, even in response to a starfish stimulus (Wilkens 1981). Similarly, in *Anodonta* the VPG can increase tonus in the posterior smooth adductor but cannot initiate relaxation in the absence of the cerebral ganglion (Barnes 1955). In the scallop, valve gape decreases following transection of the CVCs and any subsequent valve adductions decay with a long time course. Thus, even though the motor neurons innervating the smooth adductor muscle originate in the VPG, the cerebral ganglia are required for their normal function. The loss of the cerebral ganglia therefore inhibits swimming on two accounts. First, they appear to contain integral components of the swim motor circuit or to exert a required influence over its operation. Second, relaxation of the smooth muscle, which is responsible for the wide gape of the valves prior to a swim, and which must be sustained if the valves are to reopen rapidly, is blocked. That the smooth muscle does not relax following isolation of the cerebral ganglia by itself makes swimming impossible.

Earlier studies also emphasise the role of the cerebral ganglion. For example, Buddenbrock (1911) has shown that scallops respond asymmetrically to gravity due apparently to the function of the statocysts, sensory structures associated with the cerebral ganglia. Scallops suspended by a thread attached to either the dorsal or ventral margin of the shell generate movements that result in the left valve becoming uppermost, a similar result to that obtained by the righting reflex. This behaviour assumes differential control

of the mantle curtain by the statocysts and cerebral ganglion, direct for dorsal regions and indirect via the VPG for the remainder of the mantle.

As indicated previously, the adductor muscle is innervated by motor neurons located in the VPG; efferent discharges coordinating mantle and gill movements also stem from this ganglion. The jump response is to an extent a reflex barrage of excitatory efferent activity in these motor pathways, although cerebral input is required as well for the release of tension in the smooth adductor muscle. The neural mechanisms are less certain for the rhythmic bursts of activity which underlie swimming. Mellon (1969) attributes swimming to the output of a relaxation oscillator in which stretch receptors located in the fast adductor, and activated when the muscle is stretched, in turn activate motor neurons to the striated muscle. Swimming begins when valve gape is adequate to discharge the stretch receptors and is maintained by subsequent afferent bursts triggered at each cycle of valve abduction; swimming is terminated either by stretch receptor adaptation or when the oscillator is damped by coactivation of the smooth adductor muscle.

The relaxation oscillator model of swimming is based on a simple myotatic reflex. However, evidence for a reflex mechanism is as yet circumstantial. For example, even though sudden stretch (controlled by a solenoid) elicits a transient electrical response in the striated muscle (Mellon 1969), the receptors which trigger this reflex have not been identified. The reflex activity, which appears as a synchronous muscle spike, is variable in number, amplitude, and latency but has been recorded during stretch sequences of up to 21 consecutive cycles.

More recently it has been shown that swimming sequences can be initiated without stretching the adductor muscle (Wilkens 1981). In the intact animal, for example, a swim sequence can be initiated by a starfish stimulus when the valves are near maximally adducted (Fig. 5.22). In related experiments in which the smooth muscle nerves had been cut, that is, where the smooth muscle relaxation phase of the response had been eliminated, a starfish stimulus applied to the dorsal mantle again triggered swimming. These results are interpreted as indicating that the rhythmic discharges which underlie swimming are evidence of a centralised neural circuit, specifically a central pattern generator whose neural components are derived from both the visceroparietal and cerebral ganglia and one which receives input from peripheral receptors with a sharply tuned specificity for natural predators of the scallop.

Although swim-like cyclical activity in the adductor muscle can be elicited under conditions that would fail to excite stretch receptors in the muscle, the frequency of swim adductions is less than the usual 3–5 Hz. It is likely therefore that sensory elements are incorporated at some level in the pattern generator for the rhythmical swim response. Attempts to record afferent activity in the motor nerves to the smooth and striated adductor muscles have been unsuccessful (unpublished results). In the absence of stretch receptors in the muscle the most likely source of afferent input is mechanoreceptors in the mantle. An additional candidate would be the abdominal sense organ, a mechanosensory structure located on the posterior face of the adductor muscle near the anal aperture. Although these receptors are known to be sensitive to vibrations (Zhadan and Semen'kov 1984), their low threshold sensitivity (0.006 μm) may also permit the monitoring of muscle movements. As with the source, the exact role of sensory elements in the pattern

generator is unknown, although integration of sensory feedback as a timing mechanism seems most likely. Sensory, as well as premotor and motor neurons, are recognised components of oscillating neural circuits in other organisms (Delcomyn 1980; Grillner 1985; Reye and Pearson 1987).

The central role of the cerebral ganglion in escape responses and swimming is summarised by a diagram of the neural components relevant to these behaviours (Fig. 5.11, Wilkens 1981). Descending activity from the cerebral ganglia is essential not only for the rhythmical efferent discharges in VPG nerves to the striated muscle, but for the activation of afferent pathways innervating the smooth muscle, specifically those that are responsible for releasing tension in the smooth muscle prior to swims and jumps. In the latter instance, where the response is triggered by peripheral receptors that communicate directly with the VPG, neural pathways that ascend to the cerebral ganglia are required as well.

ACKNOWLEDGMENTS

Some of the unpublished results were obtained while the author was a Visiting Research Professor at the Whitney Laboratory for Experimental Marine Biology, and while supported by a grant from the Whitehall Foundation, Inc. A critique of the manuscript by Deforest Mellon, Jr., assistance with translation of reference material by Raissa Berg, and with photography by John Judd are greatly appreciated. A contribution (No. 280) from the Tallahassee, Sopchoppy and Gulf Coast Marine Biological Association.

Chapter 6

Reproductive Physiology

Bruce J. Barber and Norman J. Blake

6.1 INTRODUCTION

Reproduction is an important aspect of the life history of any species and having an understanding of reproductive processes is central to the management of any commercial fishery. This is particularly true for the Pectinidae, which in many instances have meat (adductor muscle) weights (and thus yields) that vary seasonally in relation to gametogenesis and spawning. Thus, a trade-off is sometimes made between yield per unit effort and reproductive potential. For short-lived species in which annual recruitment is dependent on the reproductive success of the previous year class, it would seem prudent to regulate harvesting to maximise reproductive output. A good example of this is the bay scallop (*Argopecten irradians*) fishery along the east coast of the United States for which harvest each year is delayed until after spawning has been completed. The availability and quality of roe-on product obviously changes seasonally in conjunction with gonad maturity. Knowledge of spawning periods is important for understanding and predicting recruitment events and maximising the collection of scallop spat for enhancement or culture. Production of the Japanese scallop, *Patinopecten yessoensis*, in Mutsu Bay, Aomori Prefecture, is the ultimate example of this approach. An understanding of reproductive physiology is also critical for the successful hatchery production (especially conditioning and spawning of broodstock) of any species.

Several important reviews of molluscan reproduction currently exist. Fretter and Graham (1964) reviewed reproduction in the entire phylum, while Purchon (1977) concentrated on reproduction in freshwater bivalves. Seed (1976) reviewed reproduction in the Mytilidae. Sastry (1979) provided a comprehensive review of reproductive physiology in bivalves (excluding the Ostreidae). Andrews (1979) reviewed reproduction in the Ostreidae. Mackie (1984) summarised molluscan reproduction in both marine and freshwater environments. These reviews attempted the difficult task of describing a basic physiological process in a very diverse group of organisms. This often necessitated sacrificing either detail on a specific topic or completeness of coverage (either number of topics covered or number of species included).

This chapter is an update of Barber and Blake (1991), an attempt to summarise the current state of knowledge of reproductive physiology in the Pectinidae. The justifications for continuing this effort are just as valid today as they were ten years ago. Scallops are a diverse, but ecologically and commercially important group of marine bivalves that are sufficiently unique from a reproductive standpoint to deserve discrete attention. Second, significant contributions to the body of knowledge have been made

during the last decade and need to be included. Third, much of what we have learned of the basic processes of reproductive physiology can be applied to the commercial culture of scallops, a rapidly expanding sector of the global aquaculture industry. Therefore, this chapter will concentrate on the description of gametogenic cycles, the factors (both endogenous and exogenous) that influence gametogenesis and spawning, the allocation of energy for gamete synthesis (energy metabolism), and the extrapolation of this information to critical aspects of commercial aquaculture, namely broodstock conditioning and spawning.

6.2 GAMETOGENIC CYCLES

6.2.1 Definition

Scallops, like other marine bivalves, have reproductive cycles that include periods of gamete formation, spawning, fertilisation, larval development, settlement and metamorphosis, and growth to reproductive maturity. Cycles of gametogenesis (the focus of this chapter) occur on a regular basis throughout the adult life of scallops and include a vegetative period followed by periods of differentiation, cytoplasmic growth, vitellogenesis (maturation), spawning (release of gametes), and resorption of unspawned gametes, all of which affect the relative size of the gonad (Fig. 6.1). Various exogenous and endogenous factors determine the timing and duration of these events for a particular species at a particular location and time. Thus, the reproductive cycle can be considered a genetically controlled response to the environment (Sastry 1979).

6.2.2 Means of Assessment

Several means of assessing gametogenesis in scallops have been utilised. Some of these are applicable to all bivalve species, and some are uniquely available to scallop biologists. The anatomy of the scallop is such that the gonad is easily visible and anatomically distinct from the rest of the visceral mass. As the gonad matures, macroscopic changes are readily visible. It increases in weight and size and becomes rounder in cross section as gametes become larger and more numerous. Also, as the sexes differentiate and gametogenesis proceeds, male gonads attain a cream colour and female gonads become reddish. After spawning and the release of gametes, gonads become smaller, flatter in cross section, colourless, and watery in appearance. Scallop gonads can thus be characterised as either empty, filling, full (mature), partially spawned, or spent, based on external appearance (Fig. 6.2). Similarly, microscopic changes are occurring within gonadal tissue as gametes develop, mature and are spawned. Both external and internal features have been used in varying degrees to assess reproduction in scallops (see Table 6.1).

Figure 6.1. Generalised (annual) gametogenic cycle indicating various stages of development relative to gonad size.

Figure 6.2. Macroscopic changes in the gonad of *Pecten maximus*: Stage I, developing; Stage II, differentiated; Stage III, recovering; Stage IV, filling; Stage V, half-full; Stage VI, full; Stage VII, spent (After Mason 1958a).

6.2.2.1 Visual observation

The most widely used (and simplest) method of assessing gametogenesis in scallops has been via gross visual examination of the gonads. Observations were made as to the relative size, shape ("condition"), and colour of the gonads of several species (Tables 6.2, 6.3 and 6.4). Mason (1958a) arbitrarily divided gonads of *Pecten maximus* into eight stages of maturity, on the basis of external appearance. Similarly, Naidu (1970) presented nine stages of gonad development for *Placopecten magellanicus*. Citing the difficulty in differentiating between undeveloped adults and virgin juveniles, Davidson and Worms (1989) recognised just four stages of gonad development for *P. magellanicus*.

In some instances, colour changes in the female gonad were assessed through more elaborate comparisons with colour standards. Tang (1941) used the "Colour Standards and Colour Nomenclatures" (Robert Ridgeway, Washington, 1912) to determine gonad development in *Pecten maximus*, and noted that as the gonad matured, the percentage of red hue gradually increased. The "Pantone Color Specifier" (Pantone Matching Systems of Pantone, Inc., New York) was used by Miller et al. (1979) to assess ovarian development in *Argopecten gibbus*. Gross visual examination of scallop gonads is the simplest method of assessing reproduction as it involves fresh material with no preparation. However, it only provides a rough estimate of overall gonadal development and no information on gamete development *per se*.

By examining fresh gonadal smears microscopically, more direct information can be obtained as to the development and viability of gametes. Spawning and fertilisation success is correlated with gamete maturity. The degree of motility of sperm and shape and size of ova was used to assess gamete maturity in *Chlamys* spp. (Reddiah 1962; Wiborg 1963) and *Placopecten magellanicus* (Naidu 1970). Bull (1976) also incorporated gonadal smears into his study of reproduction in *Pecten novaezelandiae*. Tang (1941) examined gamete viability in *P. maximus* by attempting artificial fertilisation in the laboratory. This approach provides a measure of gamete viability, but like macroscopic examination of the gonad, is only qualitative in nature.

6.2.2.2 Gonad mass and index

The anatomically distinct gonad of the scallop allows for easy removal from the rest of the soft tissue. Thus a fairly simple but effective means of assessing the timing, duration and extent of gametogenesis in scallops is to determine mean gonad mass (weight, g) on a regular basis throughout the year (e.g., Barber and Blake 1981; Barber et al. 1988). Dry weights are preferable to wet weights as water content varies seasonally. As gonad size is related to scallop (size) age (see Schick et al. 1992), it is necessary to sample individuals of a fairly discrete size range (e.g., Barber et al. 1988) or determine the gonad weight of a "standard" scallop by regressing gonad weight on shell height over a large size range (e.g., Dredge 1981; Robinson et al. 1981). Gametogenic cycles have been determined using gonad weights for several species of scallops, as indicated in Tables 6.2, 6.3 and 6.4. Bricelj et al. (1987) used ash-free dry weights to eliminate the contribution of inorganic intestinal components to gonad weight. Besides being useful for determining

periods of gamete development, gonad weights provide an ecologically meaningful, quantitative estimate of fecundity or reproductive output.

Table 6.1

Macroscopic and microscopic characteristic of gonads of *Pecten maximus* in various stages of maturity (after Mason 1958a).

Gonad Stage	External appearance of gonad	Cytological details
Stage 0 Immature	Small, flat; transparent, colourless	Some connective tissue; narrow tubules with primary germ cells give rise to follicles
Stage I Developing	Growing; minute follicles visible; fawn-coloured; no sexual differentiation	Follicles growing; male follicles lined by spermatogonia; female follicles have oogonia; young oöcytes (up to 30 µm)
Stage II Differentiated	Growing; obviously differentiated into testis (white) and ovary (fawn)	Spermatazoa appear at centre of male follicles; many half-grown oöcytes (30–60 µm) in female follicles
Stage III Recovering	Larger, thicker; flabby, containing free water; testis white and ovary bittersweet orange	Male follicles contain more spermatazoa, but loosely packed; mostly growing oöcytes in female follicles
Stage IV Filling	Still larger and thicker; colouring brighter (testis white and ovary orange to pink)	Spermatogonia, spermatocytes and few spermatids; half-grown and few larger (60–80 µm) oöcytes; little connective tissue
Stage V Half-full	Thicker, firmer; brighter (testis white and ovary pink)	Lumina full of spermatazoa and almost fully grown oöcytes; very few oogonia and little connective tissue
Stage VI Full	Large, thick, firm; highly coloured (testis cream and ovary grenadine)	Follicles maximum size; male follicles packed with spermatazoa; female follicles packed with 80–90 µm polygonal oocytes
Stage VII Partially Spent or Spent	Dull, thin, collapsed; containing much free water; follicles empty; sexual differentiation may be lost	Follicles smaller, containing large spaces; few residual spermatocytes and oocytes

Table 6.2

Major spawning periods reported for various populations of pectinid species. Means of assessing reproductive status include **GO** (gross observation), **MO** (microscopic observation), **GW** (gonad weight), **GI** (gonad index), **H** (histology, with oocyte measurements (**Oo**) or sterological measurements (**s**)), **L** (larval abundances), and **S** (spat abundances).

The gonad index (GI) or gonosomatic index (GSI), which expresses gonadal mass as a proportion of total body mass is also used extensively to define gametogenic cycles in scallops:

$$GI (GSI) = [\text{Gonad Weight (g)} / \text{Total Tissue Weight (g)}] \cdot 100 \quad (1)$$

Both wet and dry tissue weights can be used, but dry weights are preferable to eliminate the variability in water content encountered both seasonally and among the different tissues. Latrouite and Claude (1979) calculated GI as the percentage of gonad weight to remaining tissue weight rather than total tissue weight. For either ratio, GI is affected by changes in mass of either gonadal or somatic tissues. Gonad indices were used to assess gametogenesis in several species (Tables 6.2, 6.3 and 6.4).

The use of gonadal indices for assessment of relative gametogenic state assumes that the following conditions are met: 1) the allometric relationship between gonad and total tissue mass does not change over the size range of the population studied; 2) the slopes of the allometric growth equations for the gonad and total tissues are similar, and; 3) the mass of the non-gonadal tissue does not change over time. Bonardelli and Himmelman (1994) examined these assumptions for body component indices of *Placopecten magellanicus* ranging in shell height from 29–153 mm at two sites, and found that they were not met due to differences between maturing and fully mature individuals. Instead, it was recommended that gonadal mass be scaled to maximum shell height using a gonadal mass index (GMI), where b is the slope of the regression of gonadal mass to shell height for mature individuals and k is a constant to obtain a value greater than zero (Bonardelli and Himmelman 1994).

$$GMI = [\text{Gonadal Mass} / (\text{Shell Height})^b] \cdot k \quad (2)$$

An index relating gonad weight to shell height (rapport gonado-hauteur, RGH) has been used to monitor reproduction in *Chlamys varia* (Perodou and Latrouite 1981; Burnell 1983) and *Pecten maximus* (Wilson 1987):

$$RGH = [\text{Gonad Weight (g)} / \text{Shell Height}^3 \text{ (mm)}] \cdot 10^3 \quad (3)$$

Since scallops are not spherical, however, the use of the cube function in the denominator is questionable. It is important to note that both GI and RGH indices provide only relative estimates of gamete production. This subtle but important distinction separates gonad index from gonad mass as a means of assessing gametogenic stage and output.

6.2.2.3 Histology

The methods discussed so far, although simple, fast, and inexpensive, do not provide the ability to examine cytological changes occurring within the gonad. Histological preparation of gonadal tissue, although costly and time consuming, provides the means to examine and assess gamete development definitively. For example, a decrease in gonad

mass or index, which may occur as the result of either spawning or resorption of gametes, can only be distinguished histologically. Although gametogenesis is a continual process, most investigators have ascribed developmental stages to certain cytological features, which are generally recognised in all bivalve molluscs. For example, Mason (1958a) arbitrarily divided gonads of *Pecten maximus* into eight stages of maturity, on the basis of external appearance and cytological details (Table 6.1; Fig. 6.2). Unfortunately, determination of these stages tends to be subjective and there is little agreement as to the number of stages that should be included. Complete cytological descriptions of gamete development (with micrographs) are also provided by Bull (1976) for *P. novaezelandiae*, Sastry (1961) for *Argopecten irradians*, Naidu (1970) and Davidson and Worms (1989) for *Placopecten magellanicus*, Dredge (1981) for *Amusium japonicum balloti*, and Burnell (1983) for *Chlamys varia*. Histology has been employed to varying degrees by other investigators, as indicated in Tables 6.2, 6.3 and 6.4.

In addition to qualitative information, histological preparations can also be used for generating quantitative data. For example, Burnell (1983), Sause (1987), and Wilson (1987) assigned numerical values to developmental stages so that a mean "histological index" could be calculated for each sample. Mean oöcyte diameter, obtained from histological sections, reflects the reproductive cycle, as oöcytes gradually increase in size as they develop, reaching a maximum size prior to spawning. Mean oöcyte diameter decreases sharply after spawning, as mostly larger, mature ova are released (Fig. 6.3). Thus mean oöcyte diameters were used to monitor gamete development in *Argopecten irradians* (Sastry 1970a; Barber and Blake 1981, 1983; Barber 1984), *Hinnites giganteus* (Lauren 1982), and *Placopecten magellanicus* (Barber et al. 1988). Lasta and Calvo (1978) measured follicle diameter as well as oöcyte diameter to follow the reproductive cycle of *Chlamys tehuelpcha*. Mean oöcyte diameter, however, was not effective for defining gametogenic cycles in *C. varia*, as partial spawning and the development of new oöcytes occurred simultaneously (Burnell 1983). Since oöcytes are rarely circular in histological sections, measurement of mean area of oöcytes probably more accurately reflects oöcyte development than mean oöcyte diameter (e.g., Barber 1996). For either approach, however, there should be some standardisation of the number of microscopic fields observed from each section, how they are chosen, the number of oöcytes measured, and which oöcytes are measured (e.g., only those sectioned through the nucleus).

The application of stereological techniques to histological preparations can provide additional quantitative information in the form of volumetric ratios (Freere and Weibel 1966; Weibel et al. 1966). Thus gamete volume fractions were determined and applied to the study of gametogenesis in *Chlamys islandica* (Sundet and Lee 1984), *Patinopecten caurinus* (MacDonald and Bourne 1987), *Pecten maximus* (Lubet et al. 1987), and *Placopecten magellanicus* (MacDonald and Thompson 1986, 1989; Beninger 1987). This takes advantage of the fact that as gametogenesis proceeds, follicles become increasingly filled with gametes, and gonadal tissue as a whole is increasingly comprised of gametes. Estimation of volume fractions of multiple cytological features (e.g., connective tissue, follicle or lumen space, developing gametes, mature gametes, and resorbing gametes) over the course of an entire gametogenic cycle provides additional insights into gametogenic processes, including nutrient transfer and growth and development of gametes.

Figure 6.3. Reproductive cycle of *Argopecten irradians* as defined by mean (± 1 SD) oocyte diameter. (From Barber and Blake 1981).

6.2.2.4 Abundance of larvae and spat

The presence and abundance of two other life stages of scallops have been used to indirectly estimate spawning periods. Seasonal peaks in larval abundance were used to determine spawning times for *Chlamys opercularis* (Fullarton 1889), *Argopecten irradians* (Gutsell 1930), *A. purpuratus* (Wolff 1988), *Pecten maximus* (Tang 1941), *Patinopecten yessoensis* (Yamamoto 1950, 1951b, 1953, 1968), *Placopecten magellanicus* (Naidu 1970), *Chlamys zelandiae* (Booth 1983), and *C. varia* (Burnell 1983). DiBacco et al. (1995) used the presence of larvae to confirm spring spawning of *P. magellanicus*. Similarly, the occurrence of spat (post-settlement juveniles) was used to infer spawning times for *C. opercularis* (Fullarton 1889), *C. varia* (Burnell 1983), *A. irradians* (Gutsell 1930; Marshall 1960), *A. gibbus* (Allen 1979), *A. purpuratus* (Wolff 1988), *P. yessoensis* (Yamamoto 1950), and *Pecten novaezelandiae* (Bull 1976). Although occurrence of larvae indicate spawning and fertilisation have occurred, absence of larvae does not necessarily indicate an absence of spawning activity. Also, larval settlement and metamorphosis, resulting in the occurrence of spat, is highly dependent on environmental conditions. Therefore, this approach, although not reflective of the events

leading up to spawning, can provide some indication of spawning periods and the relative success of spawning and early life history stages.

All of the means of assessing reproduction in scallops have inherent advantages and disadvantages. The most complete approach would be to employ at least two methods, one quantitative (gonad weight or index) and one qualitative (histology). The histology is necessary for verification of reproductive events pertaining to gamete development not discernible by the other methods (see Beninger 1987). Total gamete weight can be calculated by multiplying gamete volume fraction by gonad weight (MacDonald and Thompson 1986).

6.2.3 Variations in Gametogenic Cycles

The events that occur in the reproductive cycle of a population include activation, growth and gametogenesis, ripening of gametes, spawning, and an inactive or "resting" period (Sastry 1979). Spawning periods, because they represent the culmination of the reproductive process and are definable by all the methods outlined above, provide a convenient focus for comparing gametogenic cycles. Within a population, scallops tend to develop and spawn synchronously. There are, however, inter- and intra-specific differences with respect to the frequency and timing of spawning as well as the duration of spawning activity (Tables 6.2, 6.3 and 6.4). There are also differences in the amount of gametogenic material produced (fecundity). Within a species, environmental differences between years and locations most likely result in the observed differences in reproductive success and recruitment. Genetic variation also contributes to the variability in gametogenesis between populations and species.

6.2.3.1 Intra-specific variations

Variations in the timing of gametogenic cycles between years have been observed for several species of scallops. The timing of gametogenic events was consistent between years for *Pecten novaezelandiae* (Tunbridge 1968; Bull 1976), *Amusium balloti* (Heald and Caputi 1981), *Argopecten irradians* (Barber and Blake 1983), *Pecten alba* (Sause 1987), *Pecten maximus* (Lubet et al. 1991), *Placopecten magellanicus* (Parsons et al. 1992), *Chlamys islandica* (Thorarinsdóttir 1993), and *Chlamys asperrima* (Zacharin 1994; O'Connor and Heasman 1996). Spawning occurred at similar times of the year, but differences in fecundity were observed between years for *C. islandica* (Skreslet 1973) and *Chlamys varia* (Shaffee and Lucas 1980). Differences between years in the timing or duration of spawning activity occurred for *P. maximus* (Mason (1958a), *P. magellanicus* (Naidu 1970; Davidson et al. 1993), and *Argopecten gibbus* (Miller et al. 1979). Differences between years in the timing of spawning and fecundity of *P. maximus* occurred at each of two sites (Wilson 1987; Strand and Nylund 1991). Spawning periods of *C. varia* (Lubet 1959) and *Pecten novaezelandiae* (Nicholson 1978) also varied between years. Egg diameter varied between years for *P. magellanicus* (MacDonald and Thompson 1986). On Georges Bank *P. magellanicus* was found to have a biannual spawning cycle, with a primary spawning event in the fall and a temporally erratic spring

spawning event (DiBacco et al. 1995). In the mid-Atlantic, inter-annual variation in the timing, duration and magnitude of spawning in *P. magellanicus* also occurred, with a dominant spawning event in the spring and an unpredictable spawning event in the fall (Kirkley and DuPaul 1991; Schmitzer et al. 1991). Maximal gonad weights and indices of *A. irradians* were lower in a year when salinity was reduced as a result of a hurricane (Bologna 1998). Variations between years in spawning intensity (% gametes released) resulted in variable recruitment in populations of *Patinopecten yessoensis* (Yamamoto 1950), *P. maximus* (Lubet et al. 1991), and *C. asperrimus* (Zacharin 1994). There was an especially intense spawning event in 1983 in a population of *Argopecten purpuratus* that resulted in unusually high recruitment (Wolff 1987). Most year-to-year variation in gametogenesis can be related to environmental factors (see Regulation of Gametogenic Cycles, below).

Site-specific variations in scallop gametogenesis have been documented for several scallop species. Population differences in spawning intensity (% gametes released) or fecundity occurred for *Hinnites multirugosus* (Jacobsen 1977), *Amusium japonicum balloti* (Dredge 1981), and *Argopecten irradians* (Bricelj et al. 1987). The greatest difference in fecundity among four sites occurred over a distance of only 1.5 km (Bricelj et al. 1987). Differences between locations in the timing of spawning were seen for *Chlamys opercularis* (Fullarton 1889; Ursin 1956), *Chlamys varia* (Lubet 1959), *Pecten maximus* (Gibson 1956; Wilson 1987; Strand and Nylund 1991), *Argopecten circularis* (Villalejo-Fuerte and Ochoa-Báez (1993), and *Pecten novaezelandiae* (Nicholson 1978), but not for *Pecten alba* (Sause et al. 1987). Parsons et al. (1992) and Davidson et al. (1993) noted differences in the intensity and timing of spawning of *Placopecten magellanicus* between sites within Passamaquoddy Bay and the Gulf of St. Lawrence, respectively. The duration of spawning of *A. irradians* was found to extend into the autumn at one or more of four sites during three different years (Tettelbach et al. 1999).

Gametogenesis in scallops has been found to vary between sites of differing water depth. *Pecten novaezelandiae* spawned first in the deeper beds (28–40 m) among seven sites ranging in depth from 6–40 m (Tunbridge 1968). For *Chlamys islandica*, no differences in the onset of spawning occurred between sites having depths of 20, 40, and 50 m, but gonad index was significantly greater at the shallowest site (Skreslet and Brun 1969). In a separate study, Skreslet (1973) observed that spawning in *C. islandica* was delayed at the deepest (39 m) of three sites.

Gametogenesis in *Placopecten magellanicus* varies between sites having differing water depth. MacDonald and Thompson (1986) showed that scallops at 31 m had a reduced rate of gamete development compared to scallops at 10 m, but that the timing of spawning and size of spawned eggs was similar at both depths. Similarly, Schmitzer et al. (1991) found that *P. magellanicus* from a shallow (38–56 m) site exhibited larger gamete volume fractions than those from deeper (56–66 m). Barber et al. (1988) compared gametogenic cycles over much greater depth differences (13–20 m and 170–180 m), and found that gonad weight and gonad index for scallops of similar shell height was significantly greater at the shallower depth and that the deeper site was characterised by more resorption and less synchronous development of gametes (Fig. 6.4). Estimated fecundities ranged from $3.1\text{--}6.6 \times 10^7$ eggs per female at the shallow site and $1.4\text{--}2.4 \times$

10^7 eggs per female at the deep site, almost a threefold difference. It is not depth *per se*, but rather the factors that vary with depth, such as food and temperature that influence gametogenesis (Barber et al. 1988).

The wide geographic distribution of some scallop species makes comparisons of gametogenic cycles on a latitudinal basis possible. There are two species for which enough information exists to examine latitudinal trends in gametogenesis. *Argopecten irradians*, the bay scallop, is found in coastal bays and estuaries along the east coast of North America from Nova Scotia to Tampa, Florida (Gutsell 1930). Studies on the reproduction of this species from Massachusetts to Florida along the east coast of North America reveal latitudinal trends in the timing of gametogenic events (including spawning), the duration of spawning periods, and energetically related parameters such as fecundity and oocyte size (Table 6.3). Spawning of *A. irradians* commences as early as May in Massachusetts populations (Taylor and Capuzzo 1983), June–July in New York (Tettelbach et al. 1999), July in North Carolina (Gutsell 1930), September in Florida (Barber and Blake 1981, 1983; Barber 1984), and December–February in the northern Gulf of Mexico (Bologna 1998). Exceptions to these general trends, however, do exist. In the Northern Gulf of Mexico, even though most spawning occurs over winter, spawning can occur as early as May (Bologna 1998). Tettelbach et al. (1999) demonstrated that scallops in New York are capable of spawning as late as September–November, even though peak spawning occurs in June–July. Sastry (1970a) compared populations from Woods Hole, Massachusetts and Beaufort, North Carolina and found that gametogenesis and spawning occurred earlier in the northern (Woods Hole) population and that the timing of maximum gonad response is significantly different between the two populations. The duration of the spawning period generally increases with decreasing latitude (Sastry 1979). The maximum mean gonad index and oocyte diameter attained prior to spawning also decreased in a southerly direction (Sastry 1970a; Barber and Blake 1983). These trends were summarised by Barber and Blake (1983) as meaning that different populations of bay scallops have differing temperature requirements for the initiation of gametogenesis and spawning and that with decreasing latitude, a smaller portion of the overall energy budget is available for gametogenesis, resulting in reduced fecundity (Fig. 6.5). This was confirmed by Bricelj et al. (1987) who calculated that the size-specific fecundity of bay scallops is seven times greater in populations from New York than from Florida.

The sea scallop, *Placopecten magellanicus*, is distributed from the Gulf of St. Lawrence to Cape Hatteras in oceanic waters off the east coast of North America (MacKenzie et al. 1978). Both the timing and duration of spawning activity in this species vary latitudinally (Table 6.4). In locations north of Cape Cod (Newfoundland, Nova Scotia, New Brunswick, and Maine) spawning occurs as early as July, but primarily in August and September (Borden 1928; Welch 1950; Dickie 1955; Naidu 1970; Thompson 1977; Robinson et al. 1981; MacDonald and Thompson 1986, 1988; Beninger 1987; Barber et al. 1988; Parsons et al. 1992; Davidson et al. 1993). Spawning occurs primarily in September–October on Georges Bank, although a secondary spawning event in May–June may take place in some years (Posgay and Norman 1958; MacKenzie et al. 1978; DiBacco et al. 1995) and even later (October–November) off the coasts of

Figure 6.4. Reproductive cycles (mean $\pm$ 1 SD gonad weight) of scallops (*Placopecten magellanicus*) from shallow (13–20 m) and deep (170–180 m) sites. (From Barber et al. 1988).

Massachusetts and New Jersey (Posgay 1950; MacDonald and Thompson 1988). MacDonald and Thompson (1988) compared gametogenic cycles of *P. magellanicus* from sites off Newfoundland and the coast of New Jersey, USA. At the Newfoundland site, mature gametes appeared in April and spawning occurred two months earlier than at the New Jersey site. In the New Jersey population, mature gametes were present almost all year and a small decrease in gamete volume fraction in June and July suggested that a partial spawning occurred prior to final gamete development and complete spawning (MacDonald and Thompson 1988). Populations further south (New Jersey to North Carolina) are characterised by biannual spawning periods, including dominant spring spawns and less predictable fall spawns (DuPaul et al. 1989; Kirkley and DuPaul 1991; Schmitzer et al. 1991). Thus, for both *Argopecten irradians* and *P. magellanicus*, as latitude decreases, primary spawning events occur later in the year and the duration of gametogenesis and spawning increases. This trend is supported further by the fact that tropical species, such as *Argopecten ventricosus*, have no seasonally defined gametogenic cycle (Luna-Gonzalez et al. 2000).

This raises the question as to whether observed differences in gametogenesis are due to environmental differences between years and locations, or genetic differences between populations. One way to distinguish between genetic and environmental effects is to mutually transplant individuals between two populations having differing gametogenic characteristics and observe the trends at the new locations. If the transplanted individuals

Figure 6.5. Reproductive cycles (mean oocyte diameters) of scallops (*Argopecten irradians*) from latitudinally separated populations. (From Barber and Blake 1983).

assume the characteristics of the native population, the original differences were due to variation in environmental conditions. If, on the other hand, original differences in gametogenic cycles, especially the timing of events, are maintained at the new location, genetic differentiation would be supported.

Bay scallops, *Argopecten irradians irradians*, transplanted from Woods Hole, Massachusetts to Beaufort, North Carolina, where the local scallop population (*A. irradians concentricus*) spawns later in the year, failed to survive and develop gonads (Sastry 1966b). Subsequent laboratory studies in which scallops from both locations were collected prior to gonadal development and acclimated to identical temperatures and photoperiods, showed that maximum gonad growth occurred at 15°C in the Woods Hole scallops and at 23°C in the Beaufort scallops, indicating that these two populations of bay scallops did not acclimate for gametogenesis (Sastry 1966b). When broodstock from two populations of *Argopecten ventricosus* were spawned and offspring from each source population were transplanted to both source locations, differences between stocks in both age of sexual maturity and gonad index were found at one site, also suggestive of genetic differences (Cruz et al. 2000). Scallops (*Pecten maximus*) transplanted from St. Brieuc Bay to Quiberon Bay, France, underwent gonad development in the winter in conjunction with the local population (Latrouite and Claude 1979), indicating that the St. Brieuc scallops are able to acclimate for gametogenesis in Quiberon Bay. *Pecten maximus*

transplanted as juveniles from the Bay of Brest, France and Scalpay, Scotland to the Bay of St. Briec, France, however, maintained cycles of gametogenesis and spawning characteristic of the site of origin and different from the native population (Mackie and Ansell 1993). Therefore, variation in scallop gametogenic cycles can be attributed to both environmental and genetic factors.

6.2.3.2 Inter-specific variations

The Pectinidae exhibit variation in gametogenic cycles characteristic of all marine bivalves. Gametogenesis occurs on an annual, semi-annual, or more continuous basis, and spawning takes place throughout the year (see Table 6.2). Species-specific variations in gametogenesis can only be determined by comparing populations of different species at a common site. Accordingly, Giguère et al. (1994) examined gametogenesis in *Placopecten magellanicus* and *Chlamys islandica* from the Îles-de-la-Madeleine, Canada, and found that *P. magellanicus* was characterised by a synchronous, annual gametogenic cycle, but that *C. islandica* had a more protracted spawning period, with considerable lysis of oöcytes.

Sause et al. (1987) suggested that pectinid species in the southern hemisphere spawn during the same range of calendar months as species in the northern hemisphere. In the southern hemisphere, however, these months (primarily June–October) correspond to winter-spring rather than summer-autumn periods. This would mean that scallops in the southern hemisphere initiate gamete development as water temperature is decreasing, and begin spawning when water temperature is at a minimum. This was the case for *Pecten alba*, in which peak spawning occurred 3–4 months before water temperature reached a maximum (Sause et al. 1987). *Pecten novaezelandiae* (Choat 1960), *Amusium japonicum* (Dredge 1981), and *Chlamys asperrima* (Zacharin 1994; O'Connor and Heasman 1996) also spawned primarily during the winter-spring (August–October) period. Spawning in *P. novaezelandiae* occurred in spring-early summer (Bull 1976), and both summer-autumn and spring-summer periods (Nicholson 1978). In addition, peak spawning of *Argopecten purpuratus* took place from February–May (summer-autumn) (Wolff 1988), spawning in *Chlamys tehuatla* occurred over the summer (October–January) (Lasta and Calvo 1978), and spawning in *Chlamys zelandiae* was site specific and occurred throughout the year, especially in northern New Zealand (Booth 1983). The differences in the timing of spawning of species in the southern hemisphere just noted suggest that there is no consistent pectinid gametogenic response to temperature and related environmental factors. This will be discussed further below.

6.3 REGULATION OF GAMETOGENIC CYCLES

The gametogenic cycle of scallops (as for other bivalves) is a genetically controlled response to the environment (Sastry 1970a, 1979). Reproductive response is produced through an interaction of exogenous factors (temperature, salinity, light, food) and endogenous factors (neuronal, hormonal) within an organism. After attaining a certain physiological state, an organism exposed to the necessary environmental conditions,

begins gonad growth and gametogenesis. Neuroendocrine activity plays a significant role in coordinating physiological processes within the organism to produce a reproductive response relative to the external environment. The successive events in the gametogenic cycle are affected differently by various factors (Sastry 1963, 1966a, 1968, 1970b; Sastry and Blake 1971; Blake and Sastry 1979). Although some of these factors have been investigated experimentally, most of the information has been obtained through observation, so is therefore correlative.

6.3.1 Gametogenesis and Fecundity

6.3.1.1 Exogenous regulation

Water temperature is the environmental factor most often cited as influencing bivalve reproduction (Sastry 1979). Gonad growth and gametogenesis have been correlated with seasonal variation in temperature for several pectinid species. For *Placopecten magellanicus*, gonadal differentiation began when water temperature was low ($-1-0^{\circ}\text{C}$), but food level high (Thompson 1977). Schmitzer et al. (1991) noted that gametogenesis and spawning of *P. magellanicus* occurred twice, in the spring when water temperature was decreasing and in autumn when temperature was increasing. Low temperature was not inhibitory to gametogenesis in *Pecten novaezelandiae* (Bull 1976). *Patinopecten yessoensis* initiated gonad development when water temperature was minimal (-1.5°C), and the period of gonad growth coincided with increasing temperature (Wakui and Obara 1967; Maru 1976). Gonadal maturation in *Chlamys farreri* was closely related to temperature (Liao et al. 1983). For *Chlamys varia*, gametogenesis was initiated at a temperature of $4-5^{\circ}\text{C}$ (a threshold of 70 degree-days) and the two periods of maximum gonad growth were correlated with rising temperatures and maximum chlorophyll-*a* levels; in addition, the rate of gamete development was correlated to the rate of increase in temperature (Burnell 1983). For *Argopecten irradians* from Woods Hole, Massachusetts, primary germ cells and gonial cells developed in winter and early spring, gamete differentiation began in April, and the population reached maturity in July in conjunction with an increase in temperature (Sastry 1970a). Bay scallops, *A. irradians*, from Beaufort, North Carolina, however, did not develop primary germ cells and gonial cells until spring, and differentiation of gametes occurred in conjunction with increasing temperature in May (Sastry 1966a, 1970a). A population of *A. irradians* from Tarpon Springs, Florida, underwent cytoplasmic growth in July when water temperature was near maximal (Barber and Blake 1983). Thus populations of bay scallops have differing minimum threshold temperatures for the initiation of gonad growth and gametogenesis (Sastry 1970a, 1979; Barber and Blake 1983). *Amusium japonicum balloti* responded differently in that gametogenesis started when temperature was near maximum (Dredge 1981). Similarly, the gonad index of *Argopecten purpuratus* was negatively correlated with water temperature (Wolff 1988). There was no relationship between temperature or salinity and gametogenesis for *Argopecten ventricosus* (Luna-Gonzalez et al. 2000). Thus the relationship between the timing and duration of gametogenic activity in scallops and water temperature is characteristic of a population under natural conditions. It follows that

temperature will have less influence on gametogenesis in (tropical or polar) locations where seasonal variation in temperature is minimal.

It is possible to induce gametogenesis in scallops outside the normal reproductive period by exposing them to suitable temperatures. Maturation of eggs in excised gonads of *Patinopecten yessoensis* was accelerated with thermal stimulation (Yamamoto 1951c, 1968). Gametogenesis in *Argopecten irradians* was induced out of season by exposure to 23°C; failure to complete the process, however, was attributed to inadequate food supply (Turner and Hanks 1960). Mature reproductive state was also attained in *A. irradians* by exposure to elevated temperatures in winter (even though the natural population does not mature until August) (Sastry 1961, 1963). Development of gametes of *A. irradians* to maturity can be accelerated after gametogenesis has been initiated, and the rate of development to maturation is dependent on temperature Sastry (1963). Temperature alone did not induce gonad growth in *Argopecten ventricosus*, but rather interacted with food ration and time (Villalaz 1994).

The most complete examinations of the effects of temperature on successive events in the gametogenic cycle of any bivalve are those of Sastry (1966a, 1968, 1970a) and Sastry and Blake (1971) for *Argopecten irradians*. In Beaufort, North Carolina, gamete differentiation was initiated when the temperature exceeded 20°C. Prior to the initiation of gonad growth, scallops exposed to 10, 20, and 30°C without food resorbed the gonial cells. Individuals with a minimum amount of gonadal reserves and oöcytes in the beginning growth stages, developed to maturity at both 20 and 30°C. In scallops with accumulated gonad reserves and oöcytes in the growth phase, the time to completion of gametogenesis and release of gametes decreased with increasing temperature. At 10 and 15°C, scallops failed to complete gametogenesis; at 25°C, gametes were released in 8 days, and at 30°C, gametes were released in 5 days (Sastry 1966a).

Gonad growth and gametogenesis in *Argopecten irradians* occurred under temperature conditions at which nutrient mobilisation for the gonads took place (Sastry 1966a, 1968). In scallops in the resting stage, gametogenesis began upon exposure to a minimum threshold temperature of 20°C in the presence of ample food. At the subthreshold temperature of 15°C, scallops developed oögonia, but oöcyte growth did not occur even though food was present. Upon exposure to temperatures of 20 and 25°C, however oöcyte growth began immediately. Apparently scallops require a minimum threshold temperature for activation of the oöcyte growth phase, since oögonia can develop at subthreshold temperatures, but without further differentiation. If, however, scallops with oöcytes already in the cytoplasmic growth phase are maintained at a temperature below that necessary for initiating growth, oöcyte development continues until dissolution of the germinal vesicle (Sastry 1970b). Thus temperature acts as a triggering stimulus for initiation of the oöcyte growth phase (Sastry 1968, 1970b). The temperatures required for activating oöcyte growth at the beginning of oögenesis and for attaining maturity ultimately limit the annual period of gonad growth and gametogenesis in the natural environment.

Sastry and Blake (1971) demonstrated that temperature influences the initiation of oöcyte growth in *Argopecten irradians* by regulating the transfer of nutrient reserves to the gonads (Fig. 6.6). Scallops that were injected with ¹⁴C-leucine (into the digestive

gland) incorporated more labelled amino acid into the gonads at 15°C than at 5°C. Thus the rate of nutrient transfer to the gonads depends upon the stage of gametogenesis and the temperature of exposure (Sastry and Blake 1971).

Gametogenesis is an energy demanding process, as the mobilisation of nutrients to the gonad is essential for gamete development. It is still unclear, however, whether gonad development depends on recently ingested food, stored reserves, or some combination of the two (Sastry 1979; Barber 1984). Ultimately, all energy is acquired from ingested "food", the definition of which is varied and poorly defined. Food available to scallop populations has been measured as chlorophyll-*a* (Broom and Mason 1978; Illanes et al. 1985; MacDonald and Thompson 1985; Thorarinsdóttir 1993), suspended particulate matter (Nicholson 1978), and energy content of seston (MacDonald and Thompson 1985; Luna-Gonzalez et al. 2000). In most cases, however, food level was not directly obtained, but rather inferred from available records.

Gametogenesis and fecundity of several scallop populations have been related to seasonal food levels. The reproductive period of *Patinopecten yessoensis* coincided with increasing stomach content index (i.e., food) (Maru 1976). Gonadal differentiation in *Placopecten magellanicus* occurred when temperature was low but food was abundant (Thompson 1977). The high food levels that occurred at the end of spring were necessary for oöcyte maturation in *Pecten maximus* (Lubet et al. 1987). The three spawning periods observed for *Chlamys opercularis* were attributed to the abundant food supply at that site (Broom and Mason 1978). In contrast, gametogenesis in *C. opercularis* occurred in winter when food supply was low (Taylor and Venn 1979). For *Chlamys varia*, the onset of gametogenesis coincided with maximum available food (Burnell 1983). Similarly, gametogenesis in *Chlamys islandica* was initiated after spawning when food was abundant, was arrested in autumn as food supply decreased, and was completed the following spring as food supply reached a maximum (Thorarinsdóttir 1993). Cruz et al. (2000) attributed the lack of gametogenic development in *Argopecten ventricosus* at Bahia Concepción to low primary productivity and high average temperature.

The relationship between seasonal food abundance and gonadal development varies among populations of the bay scallop, *Argopecten irradians* (Sastry 1961, 1963, 1966a, 1970a). In Alligator Harbor, Florida, gametogenesis was correlated with seasonal changes in phytoplankton production in that both rapid gonadal growth in the spring and recovery after spawning in the fall coincided with phytoplankton blooms (Sastry 1961, 1963). In Beaufort, North Carolina, gonadal growth and gametogenesis in the spring coincided with peak food levels; although food concentrations remained high all summer, the gonad index showed no increase until early autumn (Sastry 1966a, 1968). In Woods Hole, Massachusetts, the period of gonadal development in *A. irradians* did not coincide with peak food levels (Sastry 1970a). Thus the amount of nutrients mobilised for the gonad appears to depend not only on food level, but also on temperature and the basic metabolic requirements of the animal; adaptational differences with respect to the relationship of food to reproduction exist between different populations of this species (Sastry 1970a, 1979).

Figure 6.6. Oöcyte growth response in *Argopecten irradians* from Massachusetts as a function of temperature. (From Sastry and Blake 1971).

Stanley (1967) considered the relationships among food, temperature, and gametogenesis in several populations of *Pecten maximus*. Gonadal development in the spring was dependent on the rate of the winter recovery of weight that in turn was dependent on the magnitude of the food reserves accumulated during the previous summer and autumn. Over the winter, these reserves were presumably utilised for gametogenesis. Depending on the stage of recovery reached, spawning was triggered at some point during the spring rise in temperature, explaining both the differences in temperature recorded during this period and the earlier start and greater magnitude of the spring spawning period of the southern populations. The gonad then had sufficient time and food available to recover before the autumn spawning that occurred at all locations near the beginning of September, in conjunction with decreasing water temperature.

Elevated food (chlorophyll-*a*) levels and temperatures, the result of El Niño off the Chilean coast, greatly affect gametogenesis, fecundity, and recruitment in the local population of *Argopecten purpuratus*. In the years of El Niño, maximum mean gonad index was greater, spawning was synchronous and massive, and recruitment was over 3 times greater than in normal years (Illanes et al. 1985; Wolff 1987, 1988).

Sastry (1966a, 1968, 1970a) and Sastry and Blake (1971) experimentally examined the relationship between food supply and gametogenesis for *Argopecten irradians*. Scallops collected from the field at successive stages in their reproductive cycle were exposed to various temperatures and held without food in the laboratory (Sastry 1966a). During the initial stages of gonad growth and gametogenesis, starvation at 10, 20 and 30°C resulted in a decrease in digestive gland and gonad indices as well as resorption of oögonia and primary oöcytes. With minimal reserves in the gonad and oöcytes in the cytoplasmic growth phase, scallops held without food developed and released gametes at 25 and 30°C. At 15 and 20°C, however, digestive gland and gonad indices decreased and the oöcytes were resorbed. At 10°C, digestive gland and gonad indices remained the same, but the oöcytes failed to grow. Starved individuals having accumulated reserves and oöcytes in vitellogenesis released gametes at 20°C but not at 10°C. Scallops in the resting stage showed a decrease in both digestive gland and gonad indices and failed to initiate gametogenesis when starved at all experimental temperatures. Thus abundant food was necessary for gonad growth and gametogenesis in *A. irradians* since pre-stored nutrient reserves were not sufficient by themselves (Sastry 1966a). This is demonstrated by the decrease in tissue indices upon starvation, presumably as these nutrients are utilised for maintenance metabolism. Once the gonads have accumulated a minimal supply of energy reserves, however, gametes develop to maturity even though the animals receive no more food. For *A. irradians* it thus appears that gonad growth and gametogenesis occur under temperature conditions that allow nutrient mobilisation to the gonads in the presence of ample food, after basic metabolic requirements are satisfied (Sastry 1966a).

Sastry (1968) examined the relationships among food, temperature and gonad development for *Argopecten irradians* from Beaufort, North Carolina. The gonad index of scallops receiving food at 20°C increased, but the digestive gland index decreased. A slight increase in the gonad index and decrease in the digestive gland index occurred in scallops receiving food at 15°C. Both gonad and digestive gland indices decreased in starved animals at 15 and 20°C. Thus scallops held at temperatures below 20°C failed to accumulate gonad reserves, and pre-stored reserves were not sufficient to support gonad growth in the absence of food. It therefore appears that adequate food and a minimum threshold temperature (20°C) are necessary for the initiation of gonad growth and gametogenesis in *A. irradians* in North Carolina.

There have been no detailed laboratory studies examining the influence of salinity, light (day length), lunar phase, or tides on scallop gametogenesis. Sastry (1979), however, noted that gonad growth and gametogenesis in *Argopecten irradians* from Massachusetts were initiated during the spring in correlation with increasing day length, and maturity was attained when day length was maximal. In contrast, *A. irradians* from North Carolina initiated gonad growth and gametogenesis when the day length was about maximal, and matured and spawned in correlation with decreasing day length (Sastry

1979). Gonadal production in *A. irradians* was negatively impacted by a reduction in salinity related to a tropical storm (Bologna 1998). Amirthalingam (1928) noted that the percentage of ripe scallops (*Chlamys opercularis*) increased as the full lunar phase approached. A similar trend was noted for *Pecten maximus* (Tang 1941).

6.3.1.2 Endogenous regulation

Environmental factors are generally thought to stimulate an internal system regulating gametogenesis and sexual maturity. For invertebrates, an effective stimulation is received by receptors and transmitted to nerve ganglia. The neurosecretory cells in the stimulated ganglia secrete neurohormones, which regulate the physiological changes of the target organ, such as the gonad. Much of the knowledge of the role of the nervous system in bivalve reproduction has come from: 1) detection of monoaminergic and cholinergic neurons in the nervous system and gonads; 2) identification of nervous connections between the central nervous system and gonads; 3) analysis of the seasonal dynamics of monoamine levels in nervous ganglia, and; 4) experimental determination of the effects of monoamines and related compound on gametogenesis and spawning (Martínez and Rivera 1994).

The relationship between neurosecretion and gametogenesis in the Pectinidae is poorly understood, and few studies investigating these relationships exist. Based on a review of the histology of nerve cells in *Patinopecten yessoensis*, Osanai (1975) concluded that neuroproducts secreted by the large cells of the lower lobe of the cerebropleural ganglion accelerate gonad development and gametogenesis, and those from the small cells of the antero-lateral lobe of the visceral ganglion relate to gonad maturation. Accordingly, Osada and Nomura (1989) found that a seasonal variation in the level of catecholamines (noradrenaline and dopamine) in gonads of *P. yessoensis* was correlated to gametogenesis rather than water temperature, and was regulated by estrogen. Similarly, levels of prostaglandins in the hemolymph and ovary of *P. yessoensis* increased markedly during the spawning season; anti-estrogen inhibited this increase, suggesting that prostaglandins are involved in sexual maturation and that estrogen regulates production of prostaglandin in female scallops (Osada and Nomura 1990). Yamamoto (1951c, 1968), on the other hand, concluded that neither nervous nor circulatory systems were involved in the induction of maturation and ovulation in *P. yessoensis*, since only thermal stimulation was necessary for induction of these events outside the natural cycle. Substances secreted by the cerebropleural and visceral ganglia were found to be essential for controlling the annual gametogenic cycle of *Chlamys varia* (Lubet 1955). Levels of serotonin and noradrenalin increased in gonads, and levels of dopamine, noradrenalin and serotonin increased in adductor muscles of *Argopecten purpuratus* during active gametogenesis and decreased after spawning (Martínez and Rivera 1994; Martínez and Mettifogo 1998). Similarly, seasonal levels of serotonin in cerebral plus pedal ganglia and dopamine in the visceral ganglion were correlated with the gametogenic cycle of *Pecten maximus* (Paulet et al. 1993).

Blake (1972) and Blake and Sastry (1979) examined the neurosecretory cycle and its relationship to gametogenesis in *Argopecten irradians* (Fig. 6.7). Five neurosecretory

stages were identified histologically (based on changes in size, granulation, and vacuolisation of neurons) that correlated with stages of oögenesis. In Stage I a neuroendocrine was secreted that allowed nutrient accumulation. Stages II and III acted as “on-off” mechanisms controlling the transfer of nutrients to the gonad. Stage IV corresponded with growth of oöcytes to maturity, and the secretion corresponding to Stage V initiated spawning.

Blake (1972) examined the effects of starvation and temperature on the gametogenic and neurosecretory cycles of *Argopecten irradians*. During the vegetative stage, starvation resulted in the resorption of germinal epithelium at both 5 and 15°C, but the neurosecretory cycle remained in Stage I. In scallops with oöcytes in the cytoplasmic growth phase and the neurosecretory cycle in Stage III, starvation effected no change at 5°C, but at 15°C, the oöcytes advanced to vitellogenesis with corresponding changes in neurosecretory stage. Scallops undergoing vitellogenesis in neurosecretory cycle stage IV were not affected by starvation at either 5 or 15°C. When partially spawned individuals were starved, the residual gametes were resorbed and the neurosecretory cycle returned to Stage II. Prolonged starvation at the time oöcytes were initiating cytoplasmic growth, or exposure of scallops to sub-threshold temperatures in the later stages of oögenesis, resulted in neuron degeneration and atrophy (Blake 1972).

The change in neurosecretory cycle from Stage II to Stage III in *Argopecten irradians* acted as a switching mechanism, and oöcyte growth was initiated or delayed depending on ambient temperature and food conditions (Sastry 1968, 1970b; Sastry and Blake 1971; Blake 1972; Blake and Sastry 1979). Both cycles advanced only under conditions of adequate food and threshold temperatures. Progression from Stage II to Stage III may have initiated the transfer of nutrients from the digestive gland to the gonad, which was necessary for the growth of oöcytes. After the neurosecretory cycle entered Stage III, exposure to sub-threshold temperature reversed the neurosecretory cycle to Stage II and delayed oöcyte growth. Scallops that experienced threshold temperatures for a prolonged period of time and were in Stage III of the neurosecretory cycle with oöcytes undergoing cytoplasmic growth, or scallops in Stage IV with oöcytes undergoing vitellogenesis, however, did not regress in neurosecretory stage upon exposure to sub-threshold temperatures. Prolonged exposure to sub-threshold temperature of scallops with oöcytes undergoing vitellogenesis resulted in vacuolisation of the cytoplasm and lysis of oöcytes (Sastry 1966a, 1968). Neuronal degeneration in *A. irradians* was in turn correlated with the extent of oöcyte disintegration and resorption (Blake 1972).

Thus, the gametogenic and neurosecretory cycles appear to be dynamically linked for *A. irradians*, with both cycles being regulated by changes in environmental temperature. Feedback controls through the mediating neuroendocrine substances may regulate metabolism, accumulation of reserves, mobilisation of nutrients for the gonads, and gametogenesis relative to changes in the environment (Gabbott 1975; Sastry 1979). The relationships between exogenous and endogenous factors and gametogenesis in *A. irradians* are summarised in Figure 6.7.

A minimum age (or size) is required before gametogenesis can be initiated. The age of sexual maturity in the Pectinidae varies between species from 71 days for *Argopecten gibbus* (Miller et al. 1979) to 3–5 years for *Chlamys islandica* (Wiborg 1963) (Table 6.5).

Figure 6.7. Summary of exogenous and endogenous regulation of the reproductive cycle of *Argopecten irradians*. (From Sastry 1979).

There may be a physiological explanation for a minimum age at which scallops initiate gametogenesis. Sundet and Vahl (1981) found that when food was abundant, immature *C. islandica* gave priority to fast growth while mature scallops stored nutrients for the production of gametes. This allocation of energy to somatic growth by young scallops agrees with the general life history theory of increasing reproductive effort with age, and as such is most likely species specific (genetically determined). Once the minimum "physiological age" has been reached, however, initiation of gametogenesis and the length of time required to attain sexual maturity may vary with environmental conditions (Cruz et al. 2000).

Blake (1972) examined the effect of age on gametogenic and neurosecretory cycles in *Argopecten irradians*; individuals collected from the field at different stages of the annual gametogenic cycle were held at 5 and 15°C and provided food. Three-month-old scallops having primary oocytes (and in Stage I of the neurosecretory cycle) experienced no change in either gametogenic or neurosecretory stage at either temperature. Six-month-old scallops having oögonia and primary oocytes showed no increase in oocyte size or change in neurosecretory cycle stage at 5°C; but at 15°C, an increase in oocyte diameter with a corresponding advance in the neurosecretory cycle to Stages III and IV was seen. At the age of 1 year, post-spawning scallops returned to Stage I of the neurosecretory cycle for a short time before advancing to Stage II with the development of oögonia. At this point, scallops held at 5°C did not progress in gametogenic or neurosecretory stage, while scallops held at 15°C progressed to later stages in both cycles. Although *A. irradians*, like other species, can be stimulated to mature faster by exposure to increasing

Table 6.5

Age and size of sexual maturity in various species of Pectinids.

Species	Age	Shell height	Source
<i>Amusium japonicum</i>		>90 mm	Dredge (1981)
<i>Amusium pleuronectes</i>		54 mm	Liano and Aprieto (1980)
<i>Argopecten circularis</i>		35 mm	Villalejo-Fuerte and Ochoa-Báez (1993)
<i>Argopecten gibbus</i>	71 days	20 mm	Miller et al. (1981)
<i>Argopecten irradians</i>	1 year	55–60 mm	Belding (1910); Gutsell (1930)
<i>Argopecten ventricosus</i>	4–5 months	20–33 mm	Cruz et al. (2000)
<i>Chlamys islandica</i>	3–5 year	35–40 mm	Wiborg (1963)
<i>Patinopecten caurinus</i>	3–4 year		Hennick (1970)
<i>Pecten maximus</i>	2–3 year		Tang (1941)
<i>Pecten novaezelandiae</i>	1 year	>50 mm	Choat (1960); Bull (1976); Tunbridge (1968)
<i>Placopecten</i>	3 years	60 mm	Welch (1950)
<i>magellanicus</i>	1 year	23–75 mm	Naidu (1970)
		95 mm	Bonardelli and Himmelman (1994)
		>40 mm	Parsons et al. (1992)

temperatures (Sastry 1961; Turner and Hanks 1960), it appears that a minimum age has to be reached before cytoplasmic growth of oöcytes can be initiated (Blake 1972).

In summary, a combination of exogenous and endogenous factors is necessary before a gametogenic cycle can be initiated and completed. Fecundity, or the amount of gametogenic material produced, is dependent on the amount of energy available after maintenance requirements have been met. The portion of the energy budget allocated to gamete production ultimately depends on food availability. The relationship between fecundity and food supply has been examined for scallops in very few cases, as quantification of food level is beyond the scope of most studies. For *Placopecten magellanicus*, reproductive output (weight loss on spawning) was positively correlated with food concentration both between sites and between years at the same site (MacDonald and Thompson 1985). Similarly, Barber et al. (1988) found that fecundity (calculated number of ova) in *P. magellanicus* was reduced almost 3-fold in a deep-water (170–180 m) population compared to a shallow-water (13–20 m) population, presumably as the result of differing food levels at the two sites. For *Argopecten irradians*, Barber and Blake (1983) noted that maximum mean gonad indices decreased with decreasing latitude, from about 20% in Massachusetts, to 17% in North Carolina, to only 14% in Florida, in direct correlation to published values of food level (annual primary production) in the three locations. Bricelj et al. (1987) found differences in maximum gonad index and fecundity (weight loss on spawning) among four adjacent populations of *A. irradians* in New York and concluded that scallops are food limited in shallow, enclosed bays, where water circulation is restricted.

Metabolic stressors such as parasites and pollutants might reduce the amount of energy available for gamete production, negatively affecting fecundity. Parasitic castration of *Pecten alba* by a Bucephalid trematode was reported by Sanders (1966) and Sanders and Lester (1981). Total gamete weight in *Placopecten magellanicus* decreased by 60% in individuals exposed to both copper and cadmium, while doubling in control scallops over the same time period (Gould et al. 1988a).

6.3.2 Spawning and Spawning Synchrony

6.3.2.1 Exogenous regulation

Site-specific differences in the timing of spawning indicate that one or more environmental factors may act as a stimulus for the spawning process, once sexual maturation has been reached. Scallop life history strategies presumably have evolved such that for a given species in a particular location, spawning would occur at a time favourable for maximum rates of fertilisation and larval survival. Parameters potentially triggering gamete release include temperature, salinity, lunar phase, light, dissolved oxygen, pH, food level, mechanical shock, and ectocrines. These relationships have been examined by correlating spawning events to measured parameters in the field, as well as via controlled laboratory experiments.

Water temperature has been most frequently implicated in the initiation of spawning within the Pectinidae. Field studies have suggested that a minimum threshold temperature or critical temperature range is necessary for spawning to occur (Table 6.6). The temperature at which spawning is initiated, however, depends on acclimation history. Sastry (1961) acclimated mature *Argopecten irradians* to temperatures between 10.5 and 29.5°C at various times throughout the year and found that lower acclimation temperatures resulted in lower spawning temperatures. Thus the concept of a critical spawning temperature holds only for a population under a particular set of environmental conditions.

The initiation of spawning has been observed to occur with both increasing and decreasing temperatures. Spawning in *Chlamys opercularis* (Ursin 1956), *C. islandica* (Thorarinsdóttir 1993), *Patinopecten yessoensis* (Wakui and Obara 1967; Kawamata 1983), *Pecten novaezelandiae* (Bull 1976), *Amusium balloti* (Heald and Caputi 1981), and *Pecten alba* (Sause 1987) have all been associated with increasing water temperature. In contrast, *Hinnites multirugosus* (Jacobsen 1977) and *Argopecten gibbus* (Miller et al. 1981) spawned in conjunction with decreasing water temperature. In the case of *Pecten maximus* and *Placopecten magellanicus*, spawning in the spring occurred when water temperature was increasing and spawning in the fall occurred when water temperature was decreasing (Stanley 1967; Naidu 1970). *Argopecten irradians irradians* (the northern subspecies) spawned in response to increasing (Belding 1910; Sastry 1970a; Taylor and Capuzzo 1983; Bricelj et al. 1987) or decreasing (Tettelbach et al. 1999) water temperature, while *A. irradians concentricus* (the southern subspecies) spawned in conjunction with decreasing water temperature (Gutsell 1930; Sastry 1961, 1963; Barber and Blake 1981, 1983). Spawning of *P. yessoensis* was initiated by a sudden rise in water

Table 6.6

Temperatures at which spawning has occurred in wild populations of various Pectinids.

Species	Temperature (°C)	Source
<i>Argopecten circularis</i>	16–22	Villalejo-Fuerte and Ochoa-Báez (1993)

<i>Chlamys farreri</i>	17–18	Kalashnikova (1984)
<i>Chlamys islandica</i>	8–10	Thorarinsdóttir (1993)
<i>Chlamys opercularis</i>	7–11	Amirthalingham (1928); Ursin (1956)
<i>Chlamys varia</i>	15	Burnell (1983)
<i>Patinopecten yessoensis</i>	8.0–8.5	Yamamoto (1951b, 1953, 1968)
<i>Pecten maximus</i>	15.5–16.0	Paulet et al. (1988)
	13–15	Strand and Nylund (1991)
	7–9	Strand and Nylund (1991)
<i>Placopecten magellanicus</i>	8–11	Posgay and Norman (1958)
	4–16	Bonardelli et al. (1996)

temperature caused by a strong warm-water current flowing into Mutsu Bay (Yamamoto 1950, 1951a, 1951b). In years that this occurred, larvae and spat were found in the water, but in years when these conditions did not occur, spawning did not take place and mortality resulted (Osanai 1975; Kawamata 1985). Maru (1985) suggested that *P. yessoensis* spawns when cumulative water temperature over 2.2°C reaches 285 degree-days. In Norway, the seasonal influx of meltwater establishes thermoclines over populations of *Chlamys islandica*; the movements of these differing water masses with the tides produce sudden temperature changes (either increases or decreases) that trigger spawning (Skreslet 1973; Skreslet and Brun 1969). In Iceland, *C. islandica* spawned when temperature was increasing from 8–10°C, in conjunction with maximum chlorophyll-*a* levels (Thorarinsdóttir 1993). The intrusion of colder water from offshore may initiate spawning of *Argopecten gibbus* in the vicinity of Cape Canaveral, Florida (Miller et al. 1981). Bonardelli et al. (1996) examined the relationships of spawning of *P. magellanicus* to environmental factors over eight years and found that all but one of 33 spawning events were associated with temperature change (25 coincided with an increase in water temperature associated with downwelling, seven coincided with fluctuations at high mean temperatures, and one coincided with decreasing water temperature). It thus appears that the influence of temperature on spawning in scallops depends more on the magnitude of change occurring over a short period of time period, rather than on the direction of change.

More precise information on the influence of temperature on spawning in scallops has been obtained in laboratory experiments. *Argopecten irradians* was induced to spawn by

raising water temperature to 30–32°C and then lowering it to 22–28°C (Outten 1959; Sastry 1963). Spawning was also initiated in *Pecten albicans* by raising water temperature (Tanaka and Murakoshi 1985). *Patinopecten yessoensis* was induced to spawn by raising water temperature by 5°C, from 14–15°C to 19–20°C in 2–3 hr and raising the pH from 8.1 to 8.2–8.5 (Kinosita et al. 1943). Yamamoto (1951a, 1951b, 1953, 1968) found that spawning in *P. yessoensis* was induced by a sudden rise in temperature (as little as 0.5–1.0°C) and that raising the pH had no effect. After a series of trials involving several potential stimuli, Nicholson (1978) found that spawning in *Pecten novaezelandiae* was most effectively induced by slowly raising the temperature 5–7°C above ambient and then lowering the temperature to ambient.

In general, the strength of the stimulus needed to effect spawning decreases as maximum ripeness is attained. For *Argopecten irradians*, the minimum temperature required for spawning decreased as oöcytes become more developed (Sastry 1966a). Individuals with oöcytes in the beginning of the cytoplasmic growth phase failed to release gametes at 10, 15, and 20°C. At a later stage of development, individuals held at 20°C spawned, while those held at 15 and 10°C did not. Sastry (1966a) also noted that spermatozoa were released at a lower temperature than ova.

Limited information suggests that environmental parameters other than temperature can also influence spawning in scallops. Spawning in *Chlamys opercularis* (Amirthalingam 1928) and *Pecten maximus* (Tang 1941; Mason 1958a; Stanley 1967) has been associated with lunar phase. The lunar influence on spawning may be indirect, however, with the actual stimulus being provided by temperature changes associated with spring tides (Mason 1958a; Stanley 1967; Burnell 1983). Parsons et al. (1992) found a significant relationship between spawning of *Placopecten magellanicus* and lunar/tidal cycles which in turn would result in changes in temperature, food supply, and current speed, any of which could stimulate spawning. Naidu (1970) noted that spawning of *P. magellanicus* occurred in conjunction with periods of physical disturbance associated with high winds and rough seas. In support of this, Desrosiers and Dubé (1993) found that flowing seawater induced spawning in 93% and 100% of male and female *P. magellanicus*, respectively. Spawning of *Patinopecten yessoensis* was not related to lunar phase (Yamamoto 1952), but was correlated with the progression of the plankton community, following the abrupt seasonal change in water temperature (Yamamoto 1952, 1953). Yamamoto (1951a) found that decreasing the dissolved oxygen and pH of the water inhibited spawning of *P. yessoensis*. Lower salinity associated with the influx of meltwater may have provided a spawning stimulus for *Chlamys islandica*, but the effects of salinity changes could not be separated from the effects of simultaneous temperature changes associated with the meltwater (Skreslet 1973). Gametes of the opposite sex stimulated spawning in *Chlamys varia* (Lubet 1951). Thermal stimulation of spawning was more effective than mechanical stimulation of spawning in *C. varia* when combined with extracts of gametes (Lubet 1959). The presence of gametes in the water apparently provides a chemical stimulus (ectocrine) that triggers a spawning response in mature individuals.

Synchronous release of gametes of both sexes maximises the likelihood of successful fertilisation and the production of larvae. The degree of synchronisation of spawning,

however, varies among species and within populations of the same species both between locations and years. The environmental factors responsible for bringing the population to a mature stage so that spawning can be as synchronous as possible have not received much attention. Exogenous factors may synchronise gonad development in members of a population at an early stage of gametogenesis so that spawning synchrony can be maximised, provided the proper spawning stimulus exists.

Experimental studies on environmental regulation of the neurosecretory cycle and gonad development in *Argopecten irradians* indicate that the controlling mechanisms within the organism may be responsive to environmental influences at the beginning of the cytoplasmic growth phase of oocytes (Sastry 1966a, 1968, 1970b; Sastry and Blake 1971; Blake 1972; Blake and Sastry 1979). A population responding to environmental influences would initiate gonad development at the same time and progress synchronously toward maturity. However, oocytes of different sizes occur within the gonads of individual scallops throughout the period of gonad development, both in the field and in the laboratory. Variation in the size of oocytes size may be due to temporal differences in the initiation of cytoplasmic growth, which could be related to the amount of nutrients available for ovarian development. Although variation in development of oocytes exists within individuals, the population as a whole is synchronous in development toward maturity. Even after spawning is initiated, there is a considerable range in oocyte size, indicating that oocyte development is continuing even at this point in the cycle. Thus over the approximately eight week spawning period, the release of gametes probably occurs in pulses as reflected by the stepwise decline in the gonad index and mean oocyte diameter. If all members of the population are mature and react simultaneously to the factors inducing spawning, gametes will be released synchronously. Therefore, synchrony in spawning appears to depend on a critical state of physiological maturity of a population as a whole and on the responsiveness of the population to the exogenous factors inducing gamete release.

Variation in spawning synchrony in different years has been noted by Langton et al. (1987) for mature *Placopecten magellanicus*. They reasoned that synchronous spawning, which would allow the most effective fertilisation, might be the earliest indication of year class strength. Dickie (1955) reported that scallop abundance in any year class is correlated with water temperature six years previously. Higher temperatures might result in more favourable conditions for larvae or contribute to a more synchronous, intense spawning in *P. magellanicus*. If environmental conditions are not ideal for mass spawning, scallops may adopt a "dribble" spawning strategy thus ensuring that at least some larvae will survive (Langton et al. 1987). Similarly, early partial spawning may reflect a "bet-hedging" strategy in which at least some gametes would encounter environmental conditions favourable for development (Parsons et al. 1992).

Differences in synchrony of spawning occurred in two populations of *Pecten maximus* (Paulet et al. 1988). In the Bay of St. Brieu, maturation was synchronous and spawning was synchronous and massive. In the Bay of Brest, mature individuals were present all year and partial spawnings occurred over a five month period. Massive, synchronous spawning might result in highly variable recruitment, depending on environmental conditions at the time of spawning. Spawning over a prolonged period

decreases the likelihood of either very weak or very strong recruitment (Paulet et al. 1988), and could be an adaptation to an unpredictable environment.

Larval abundances have been related to spawning intensity and synchrony in populations of *Patinopecten yessoensis* (Yamamoto 1950, 1951b, 1968). In some years, mature gametes were retained, suggesting that a proper spawning stimulus (increased water temperature) was not received (Yamamoto 1950; Osanai 1975). Variation in local environmental conditions triggering the release of gametes in physiologically mature populations may thus play a major role in determining spawning synchrony and resultant year class success.

6.3.2.2 Endogenous regulation

Spawning is more difficult to induce in non-mature individuals than in mature individuals (e.g., Yamamoto 1968; Nicholson 1978; Malachowski 1988), suggesting that internal physiological conditions have to be met before external stimuli effectively induce spawning. Neuroendocrine control of spawning has been investigated for several species of scallops. A secretion associated with Stage V of the neurosecretory cycle was associated with spawning in *Argopecten irradians* (Blake 1972; Blake and Sastry 1979). Lubet (1955a) proposed a neurosecretory regulation of spawning in *Chlamys varia* based on the observed reduction in neurosecretory products of the cerebral ganglia in response to maximal environmental stimuli. Prior to spawning, neurosecretory products were released. Ablation of the cerebral ganglion accelerated spawning, while removal of the visceral ganglion retarded spawning (Lubet 1955b). It was thus suggested that the neurosecretion of cerebral ganglia has an inhibitory effect on spawning and that only after the dissipation of neurosecretory products does the individual become receptive to environmental factors stimulating spawning (Lubet 1955a, 1955b). Martínez et al. (1996) showed that levels of dopamine, noradrenaline and serotonin changed in nervous, muscle and gonadal tissue when spawning of *Argopecten purpuratus* was thermally induced.

Relationships between the presence of specific neurosecretory products and spawning have been investigated for *Patinopecten yessoensis*. Serotonin (5-hydroxytryptamine) effectively induced spawning of *P. yessoensis* (Matsutani and Nomura 1982; Matsutani and Nomura 1984), as well as of *Pecten albicans* (Tanaka and Murakoshi 1985) and *Hinnites giganteus* (Malachowski 1988). Methysergide (serotonin antagonist), lanthanum chloride and aspirin (inhibitor of prostaglandin synthesis) prevented induction of spawning with serotonin, providing further evidence that serotonergic mechanisms (as well as prostaglandin and dopaminergic mechanisms) are involved in scallop spawning (Matsutani and Nomura 1986). Osada et al. (1987) found significantly lower levels of dopamine in cerebral plus pedal ganglion, visceral ganglion, gills, and gonads of *P. yessoensis* after spawning was stimulated with UV irradiated seawater, suggesting that the release of dopamine is also important in the spawning of scallops. Prostaglandin levels decreased in ovaries but increased in testes of spawning *P. yessoensis*, suggesting inhibitory and stimulatory effects in female and male scallops, respectively (Osada et al. 1989).

Age may also influence the timing of spawning in scallops. Burnell (1983) found that for *Chlamys varia*, smaller (younger) individuals ripened and spawned earlier than larger (older) individuals. Also, in both the minor spring spawning and the major autumn spawning of *Pecten maximus*, individuals over the age of 8–9 years spawned later than the younger individuals (Stanley 1967). Thus, in spite of experiencing similar environmental stimuli, younger scallops in these populations spawned first, perhaps triggering spawning in the older individuals. Nicholson (1978) studied the effect of age-specific spawning responses for populations of *Pecten novaezelandiae* and found that the secondary spawn that occurred irregularly among the various sites and years involved primarily young (two year old) individuals; older individuals (>100 mm shell height) spawned less frequently and less completely. Thus the spawning characteristics exhibited by a particular population may depend to a large extent on the age structure of that population.

Research to date indicates that an external spawning stimulus is detected by specific receptors and communicated by a monoaminergic mechanism from the nervous system to the gonad, where the signal induces the action of some other compound or physiological event (e.g., adductor muscle contraction) that results in the release of gametes. There is also evidence that these neurohormonal mechanisms differ for male (primarily serotonin) and female (primarily catecholamines) scallops.

6.4 ENERGY METABOLISM

Gamete production is ultimately dependent on energy derived from ingested food. The energetic transformations that occur within a scallop after food energy is assimilated and before spawning occurs, however, are unclear. Like other marine bivalves, scallops exhibit cycles of energy storage and utilisation that are closely linked to annual cycles of gametogenesis (Gabbott 1975; Sastry 1979; Barber 1984). Although the specifics of these cycles are species and location dependent, energy is generally stored in one or more body components in the form of lipid, carbohydrate, or protein substrates when food intake exceeds basic maintenance requirements. These energy reserves are subsequently utilised to varying degrees (in conjunction with available food) to meet the energetic requirements of gametogenesis.

There are several types of information which when viewed in conjunction with gametogenesis, are relevant to the study of gametogenic energy metabolism in scallops. Changes in somatic tissue weights and indices indicate sites of energy storage. Changes in biochemical composition (lipid, carbohydrate, protein) of body components reveal which substrates contribute to energy metabolism at different times throughout the gametogenic cycle. Scallop physiological rates (oxygen consumption, carbon dioxide production, and ammonia excretion) are reflective of energy balance and substrate catabolism. The use of radiolabelled compounds helps define the energetic transformations and translocations occurring within the individual. Ultrastructural and histochemical approaches help visualise and verify specific routes and mechanisms of metabolite transfer. This section will attempt to assimilate available information that is relevant to gametogenic energy metabolism, or the manner in which assimilated energy is utilised with respect to gametogenesis in scallops.

6.4.1 Tissue Weights and Indices

Just as an increase in gonad mass (or index) is indicative of gametogenesis while a decrease signifies spawning, an increase in somatic body component weight indicates substrate accumulation or storage (growth), while a decrease is indicative of utilisation (degrowth). Changes in body component weights and indices thus have been useful for determining the relationships among growth and gametogenesis in several species of scallops. The adductor muscle of *Chlamys septemradiata* declined in weight over the winter, and reached a minimum prior to the period of gonad growth (Ansell 1974). For *Chlamys opercularis*, adductor muscle dry weight decreased in conjunction with gametogenesis (Taylor and Venn 1979). O'Connor and Heasman (1996) noted that the adductor muscle weight of *Chlamys asperrima* varied inversely with that of the gonad. The adductor muscle of *Pecten maximus* doubled in weight between March and November, but declined as the gonad increased in weight over the winter (Stanley 1967; Comely 1974). Faveris and Lubet (1991) found a similar inverse relationship between adductor muscle weight and gonad index for *P. maximus*. Weights of the digestive gland and adductor muscle of *Patinopecten yessoensis* decreased in conjunction with the increase in gonad weight (Fuji and Hashizume 1974). Lauren (1982) found that the adductor muscle index of *Hinnites giganteus* was inversely related to the gonad index. Digestive gland and adductor muscle indices in *Placopecten magellanicus* decreased as the gonad index increased (Robinson et al. 1981). Similarly, Schick et al. (1992) found an inverse relationship between weights of adductor muscle and gonad body components of *P. magellanicus*. For *Argopecten irradians*, Hickey (1978) noted that the adductor muscle index decreased during the period of gonad maturation and spawning and that adductor muscle weight gain occurred after spawning, while Sastry (1966a) found a reciprocal relationship between digestive gland and gonad indices. In the population of *A. irradians* studied by Barber and Blake (1981), adductor muscle dry weight decreased by two-thirds and adductor muscle index decreased by 18.7% over the periods of cytoplasmic growth and maturation of oöcytes (Fig. 6.8).

The importance of the scallop adductor muscle as a source of stored energy for gametogenesis and other metabolic demands becomes evident when gamete development is arrested. Scallop (*Argopecten irradians*) embryos treated with cytochalasin B to induce triploidy (effecting sterility), had adductor muscles that were 73% heavier and contained significantly more glycogen than diploid (control) scallops that underwent gametogenesis (Tabarini 1984). Similarly, Ruiz-Verdugo et al. (2000) found that triploid *Argopecten ventricosus* had significantly larger adductor muscle weights than diploids. In other words, when there is no energetic demand from the gametogenic process, energy reserves that are normally diverted to gamete synthesis remain in the adductor muscle. This approach may provide a more direct calculation of reproductive cost in scallops.

Simultaneous growth of gonadal tissue and a decrease in one or more somatic tissue weights or indices suggest that the utilisation of stored reserves is involved in the gametogenic process. For scallops, the adductor muscle appears to be the primary site of

Figure 6.8. Energy storage cycle in *Argopecten irradians* as reflected by mean (± 1 SD) body component dry weights. (From Barber and Blake 1981).

energy storage, with the digestive gland involved secondarily. The relative importance of the adductor muscle in scallop gametogenic energy metabolism, however, is site specific (Barber and Blake 1983; Bricelj et al. 1987) and may vary with environmental food levels.

6.4.2 Tissue Biochemical Composition

Biochemical analysis of scallop body components have revealed which substrates (protein, lipid, carbohydrate) are accumulated and utilised in conjunction with changes in weight of various body components with the increase in gonadal constituents associated with gametogenesis. For *Chlamys septemradiata* (Ansell 1974), *Chlamys opercularis* (Taylor and Venn 1979), and *Pecten maximus* (Stanley 1967; Comely 1974), declines in adductor muscle weight were accompanied by decreases in glycogen and protein contents and an increase in gonadal lipid content. Faveris and Lubet (1991) found an inverse relationship between adductor muscle lipid and protein (but not glycogen) contents and gonad index of *P. maximus*. Pollero et al. (1979) noted a reciprocal relationship between gonad and other tissue lipid contents in *Chlamys tehuelcha*. Glycogen stored in the adductor muscle of *Chlamys islandica* during the summer was subsequently depleted

during the winter in conjunction with gametogenesis (Sundet and Vahl 1981). A loss of glycogen in somatic tissues was correlated to gonadal development in *Chlamys varia* (Shafee 1981). Mori (1975) found that digestive gland lipid and adductor muscle glycogen levels decreased prior to gonad development in *Patinopecten yessoensis*. For *Placopecten magellanicus*, digestive gland lipid and carbohydrate and adductor muscle carbohydrate were depleted as gametes matured and gonadal lipid content reached a maximum (Robinson et al. 1981). Couturier and Newkirk (1991), however, found that only adductor muscle protein content was inversely related to gonad weight of *P. magellanicus*. Lipid, protein and glycogen levels in plasma of *P. magellanicus* increased during the period of gonad growth (Thompson 1977), suggesting that any or all of these substrates were being mobilised for gamete synthesis. For *Argopecten irradians*, the utilisation of lipid from the digestive gland was associated with initiation of the oocyte growth phase, and decreases in glycogen and protein from the adductor muscle occurred in conjunction with cytoplasmic growth and vitellogenesis and corresponding increases in protein and lipid in the gonad (Barber and Blake 1981). These relationships are shown in Figure 6.9. The authors also noted a significant correlation between decrease in adductor muscle glycogen content and increase in mean oocyte diameter, indicating that oocytes were growing as glycogen in the adductor muscle was being depleted (Fig. 6.10). A similar inverse relationship between adductor muscle glycogen content and gonad index occurred for *Argopecten purpuratus* (Martínez and Mettifogo 1998).

Additional support for the importance of adductor muscle glycogen as a source of energy for gametogenesis exists for *Placopecten magellanicus*. Gould et al. (1988b) reported that scallops from water over 110 m in depth had very low adductor muscle glycogen levels throughout the year compared to scallops from shallower depths. This corresponds with the finding of Barber et al. (unpublished) that scallops at depths of 170–180 m had smaller adductor muscles that showed little seasonal variation in weight compared to adductor muscles of scallops from depths of 13–20 m (Fig. 6.11). Similarly, there was a 66% reduction in fecundity in the deep-water population. Both of these studies supported the hypothesis that low food supply limits energy storage at greater depths. This would explain the reduced adductor muscle size and glycogen content and in turn, the reduced fecundity at greater depths. It follows that the greater the amount of energy available for gametogenesis (either from available food or reserves stored in the adductor muscle), the greater the fecundity will be.

Adductor muscle glycogen thus appears to be the energy substrate most readily stored and utilised for gametogenesis. Lipid stored in the digestive gland and lipid and protein stored in the adductor muscle may also be involved. Differences in the timing of utilisation of the various substrates suggest that they may be involved in different phases of the gametogenic cycle. Differences in the sources and timing of utilisation of various energy substrates are most likely due to either genetic differences between species or the quantity and quality of locally available food resources.

Figure 6.9. Energy storage cycle in *Argopecten irradians* as reflected by biochemical composition of (A) adductor muscle and (B) gonad. (From Barber and Blake 1981).

Figure 6.10. Relationship between glycogen content of adductor muscle and mean oöcyte diameter in *Argopecten irradians* ($Y = 20.37X + 796.6$; $r = -0.83$). (From Barber 1984).

6.4.3 Physiological Indices

Rates of oxygen consumption, carbon dioxide production, and ammonia excretion, when converted to O/NH_3 and CO_2/O_2 molar ratios provide indices of the catabolic balance between protein, carbohydrate, and lipid substrates, and thus are pertinent to the study of gametogenic energy metabolism. The ratio of moles of oxygen consumed to moles nitrogen (ammonia) excreted provides an index of the relative amount of protein to non-protein catabolism occurring at a particular time (see Barber 1984). If the amino acids resulting from protein breakdown are deaminated and totally excreted as ammonia while the carbon skeletons are fully oxidised to carbon dioxide and water, the theoretically minimum O/NH_3 ratio (indicative of exclusive protein catabolism) is 9.3. Higher values indicate a greater contribution to energy metabolism from non-protein (lipid and carbohydrate) sources. Barber and Blake (1985b) examined trends in O/NH_3 ratios over the gametogenic cycle of *Argopecten irradians* and found an increase early in the gametogenic cycle, with values decreasing later in the cycle, as glycogen from the adductor muscle was being depleted (Fig. 6.12).

Figure 6.11. Comparison of adductor muscle and gonad wet weight of *Placopecten magellanicus* at (A) shallow (13–20 m) and (B) deep (170–180 m) sites. (From Barber et al. 1988, unpublished).

Additional information on the relative contribution of the various substrates to energy metabolism is provided by the respiratory quotient (RQ), defined as the ratio of the moles of carbon dioxide produced to the moles of oxygen consumed (see Barber 1984). When carbohydrate is oxidised, all of the oxygen utilised forms carbon dioxide, resulting in an RQ of 1.0. When protein and lipid are catabolised, some of the oxygen forms water,

Figure 6.12. Seasonal variation in substrate catabolism of *Argopecten irradians* as reflected by (A) O/NH₃ and (B) RQ physiological indices. (From Barber and Blake 1985b).

resulting in RQ values of 0.79 for protein and 0.71 for lipid. An RQ greater than 1.0 indicates that carbohydrate is being converted to lipid. For *Patinopecten yessoensis*, the RQ of digestive gland tissue fell from 1.3 to 0.7 during the period of gonad development (Mori 1975). Barber and Blake (1985b) also measured RQ values of *Argopecten irradians* over the course of a gametogenic cycle and found that RQ increased from about 0.7 to 1.0 in the early stages of gametogenesis, exceeded 1.0 for most of the cytoplasmic growth period, then decreased to around 0.6 after spawning (Fig. 6.12).

The physiological indices thus reinforce the biochemical composition data by indicating relative contributions of the various substrates to gametogenic energy metabolism. In combination, these indices indicate that energy metabolism shifts from being lipid based during the initiation of gametogenesis to being carbohydrate based

during the period of cytoplasmic growth of oocytes. Additionally, RQ values during this period suggest that glycogen is being converted to lipid. Toward the time of spawning and especially after spawning, metabolism is fuelled primarily by protein.

6.4.4 Radiotracer Experiments

The use of radiolabelled compounds allows the movement and distribution of particular biomolecules to be followed over time. For studies pertaining to gametogenic energy metabolism, radiotracer experiments can provide more direct information with respect to the movement of particular substrates within the individual. Very few studies of this type have been undertaken for scallops. Sastry and Blake (1971) injected ^{14}C -leucine into the digestive gland of *Argopecten irradians* and found that in conjunction with oocyte growth, incorporation of ^{14}C into gonads one week after injection was significantly higher at 15°C than at 5°C . Vassallo (1973) fed ^{14}C lipid (*Chlorella* extract) to *Chlamys hericia* via a cannula and found that lipid activity in the gonad increased as digestive gland lipid activity decreased.

Barber and Blake (1985a) fed ^{14}C -inoculated *Tetraselmis* sp. to *Argopecten irradians* at monthly intervals over the reproductive period and observed subsequent ^{14}C incorporation into lipid, carbohydrate and protein fractions of digestive gland, adductor muscle, and ovarian tissues. It was found that the pattern of ^{14}C incorporation varied seasonally in conjunction with oögenesis (Fig. 6.13). Resting stage scallops exhibited net radiocarbon losses in ovarian fractions and small radiocarbon losses in digestive gland fractions that were equalled by gains in adductor muscle carbohydrate and protein fractions. During the period of oocyte growth, ^{14}C losses in digestive gland and adductor muscle fractions always exceeded progressive gains in the ovary. Increased carbon turnover (catabolism) of digestive gland lipid and adductor muscle carbohydrate fractions accompanied decreased turnover (anabolism) of ovarian lipid. After spawning, ^{14}C was rapidly lost from all body component fractions.

Radiotracer studies thus reinforce the patterns of energy storage and utilisation suggested by previous studies providing data on tissue weights and indices, biochemical composition, and substrate catabolism. Prior to gametogenesis, nutrients are stored in digestive gland and adductor muscle components. During cytoplasmic growth digestive gland lipid and adductor muscle carbohydrate is utilised in conjunction with an accumulation of lipid in the ovary.

6.4.5 Ultrastructure and Histochemistry

The approaches described so far are only gross indicators of nutrient storage and utilisation with respect to gamete formation, and provide little in the way of direct evidence as to how proposed metabolites are being moved within and between tissues of an animal undergoing gametogenesis. The use of histochemical techniques, in which thin tissue sections are stained to reveal the distribution of particular biomolecules (substrates and enzymes), in conjunction with histological and ultrastructural (electron microscopic) analyses, helps visualise and verify specific energetic pathways.

Figure 6.13. Relative seasonal incorporation of C^{14} by ovary, digestive gland, and adductor muscle body components of *Argopecten irradians*. (From Barber and Blake 1985a).

Gametogenesis of the scallop *Pecten maximus* is characterised by oöcyte atresia throughout the year, which reaches a maximum during vitellogenesis (Lubet et al. 1987; Dorange and Le Pennec 1989). Le Pennec et al. (1991) used ultrastructural, histological and histochemical approaches to identify sources, transfer mechanisms, and modes of incorporation of energy substrates to the developing oöcytes of *Pecten maximus*, paying particular attention to the fate of atretic oöcytes. They demonstrated that lysed material could be taken up directly by adjacent developing oöcytes via endocytotic vesicles or by gonoducts via ciliated epithelial cells with endocytic-like vacuoles. Lysed material that escapes the gonoducts through the gonopore enters the pallial cavity where it might also be taken up along the epithelia of the gonad itself by non-ciliated microvillous cells and transported to underlying tissue by amoebocyte transit cells.

It is also known that part of the scallop intestine loops through the gonad, and thus may play a role in digestion and assimilation of nutrients. The transfer of metabolites across the intestinal epithelium directly to developing gametes in the gonad was supported by ultrastructural and histochemical observations of *P. maximus* (Le Pennec et al. 1991) and *Argopecten ventricosus* (Luna-Gonzalez et al. 2000). Beninger et al. (unpublished) established that ferritin directly injected into the intestine of *P. maximus* was rapidly absorbed by the intestinal epithelium and transferred to hemocytes in the surrounding connective tissue. Ferritin-bearing hemocytes then migrated along connective tissue fibres to acini and appeared inside the acini of developing female gonads.

6.4.6 Mechanisms

Based on the available information on gametogenic energy metabolism in scallops, several mechanisms have been proposed for the cycling of available energy within an individual and its eventual transfer to and sequestration by developing gametes in the gonad. Barber (1984) suggested that three possible mechanisms are involved in the gametogenic energy metabolism of *Argopecten irradians concentricus*. The first mechanism involves the direct transfer of either stored or recently ingested fatty acids from the digestive gland to developing oöcytes in the gonad. Digestive gland lipid reaches high levels in some species prior to gametogenesis and decreases as oöcytes mature (Pollero et al. 1979; Mori 1975; Robinson et al. 1981; Barber and Blake 1981). Radioactive biomolecules move from digestive gland to gonad body components in conjunction with reproductive activity (Sastry and Blake 1971; Vassallo 1973; Barber and Blake 1985a). The existence of increased plasma lipid levels during oögenesis supports the feasibility of lipid transport between body components via the hemolymph (Thompson 1977). The second mechanism involves the conversion of carbohydrate to lipid in a manner similar to the glucose-fatty acid cycle in vertebrates. A general loss of glycogen reserves from adductor muscle tissue (which is not replaced until after spawning) often accompanies gonad lipid accumulation (Ansell 1974; Comely 1974; Mori 1975; Taylor and Venn 1979; Barber and Blake 1981; Robinson et al. 1981). High physiological indices during the early stages of gametogenesis indicate the predominance of carbohydrate catabolism and the conversion of glycogen to lipid (Mori 1975; Barber and Blake 1985b). The existence of a functional Krebs' cycle in bivalves is generally accepted, as evidenced by the presence of the carboxylic acid intermediates and enzymes involved in the cycle and the results of studies on the movement of ^{14}C from glucose through the cycle to $^{14}\text{CO}_2$ (Gabbott 1976). The third mechanism involves the breakdown of protein to indirectly support reproduction. Protein is accumulated as somatic tissue during periods of growth, and utilised over the gametogenic period, most commonly in species that undergo oögenesis over the winter when food levels are minimal and after lipid and carbohydrate reserves are depleted (Adachi 1979; Taylor and Venn 1979; Sundet and Lee 1984). In other species gametogenesis is primarily supported by available food and lipid and carbohydrate reserves so that protein is not catabolised to a great extent, or if it is, not until the other reserves are depleted (Barber and Blake 1981). This relationship is reflected by the low physiological index values obtained during later gametogenic and spawning periods (Mori 1975; Barber and Blake 1985b). Since gametogenesis is essentially complete at this point, energy derived from protein catabolism probably supports maintenance metabolism, rather than gametogenesis directly.

Le Pennec et al. (1991) proposed two additional mechanisms of energy transfer to developing oöcytes of *Pecten maximus*, including recycling of atretic oöcytes and intestinal loop transfer. Oöcytes themselves represent significant energy stores. In situations where oöcytes are lysed rather than spawned, ultrastructural and histochemical data have demonstrated that significant resorption of lytic debris occurs in the acini (via developing oöcytes), in gonoduct epithelium cells, and along gonadal epithelium (Le Pennec et al. 1991). Histochemical detection of injected ferritin in intestinal epithelium,

hemocytes, connective tissue and acini of maturing ovaries demonstrates that digestion does occur along the portion of the intestine that runs through the gonad, and that energy assimilated is subsequently moved by hemocytes to developing oocytes (Le Pennec et al. 1991; Beninger, unpublished). Figure 6.14 provides a schematic summary of all potential energy substrate sources and transfer mechanisms to developing gametes in scallops. The relative importance of these mechanisms varies between species and locations.

Additional neurohormonal control of the gametogenic cycle could occur indirectly, through control of the energy storage cycle. Martínez and Mettifogo (1998) found that when adductor muscle tissue of *Argopecten purpuratus* was incubated with dopamine, an increase in cyclic AMP occurred near the completion of oocyte maturation. An increase in monoamine concentration in the adductor muscle would stimulate production of cyclic AMP, which in turn would induce the phosphorylation of glycolytic enzymes, thus increasing the catabolism of glycogen for gamete maturation.

6.5 APPLICATIONS TO AQUACULTURE

Successful culture of any species is dependent upon a comprehensive understanding of the reproductive process. As numerous wild stocks of scallops worldwide are becoming depleted, aquaculture is seen as a way of meeting a growing demand, either through stock enhancement efforts or commercial culture (see chapters relating to aquaculture, this volume). Much of the information presented in this chapter regarding the regulation of gametogenesis and spawning is relevant to the hatchery-based culture of scallops, including broodstock conditioning, induction of spawning, and the relationship between broodstock nutrition and larval growth and survival. Properly applied, a basic knowledge of gametogenesis will help commercial hatcheries produce a consistent, high quality, year round supply of seed organisms.

6.5.1 Broodstock Conditioning

It has long been known that scallops can be “conditioned” (induced to undergo gametogenesis) outside of normal seasonal cycles by exposure to adequate temperature and feeding regimes (Turner and Hanks 1960; Sastry 1961, 1963). Both the quantity and quality of gametes produced depend on adequate nutrition. For example, Martínez et al. (1992) found that *Argopecten purpuratus* fed a diet consisting of *Isochrysis galbana*, *Chaetoceros gracilis* and *C. calcitrans* for 48 days did not become fully ripe, but that individuals placed in the ocean reached maturity and spawned in the same period. The percentage of *A. purpuratus* reaching maturity was greater for individuals fed a microalgal diet supplemented with a lipid emulsion (Navarro et al. 2000). Monsalvo-Spencer et al. (1997) found that 95% of *Argopecten ventricosus* fed a diet consisting of a 6:3:1 ratio of *Isochrysis galbana*: *Chaetoceros* sp.: *Tetraselmis suecica* reached reproductive maturity in 27 days. Gonadal dry weight of *A. ventricosus* increased significantly after being fed a high ration for 40 days (Villalaz 1994). Not only are the contents of diets important, but the delivery of those diets may also have an impact on conditioning efficiency. Racotta et al. (1998) found that continuous feeding of *A. ventricosus* with equal cell numbers of

Figure 6.14. Schematic summary of energy substrate sources and transfer mechanisms to developing gametes of scallops. 1 = ingestion of particulate matter captured and transported by the feeding epithelia (gills, Gi; labial palp complex, LP). 1a = entry of particles into diverticula of digestive gland (DG). 2 = diffusion of metabolites resulting from digestion into the hemolymph and hemocytes (H). 2a = distribution of these metabolites to various organs, including the adductor muscle (AM) and gonad (Go). 2b = hemolymphatic transfer of metabolites from the adductor muscle to the developing gametes. 2c = transfer of products of digestion within the gonad intestinal loop to the vesicular-cell hemocyte couples in intestine-acinus transfer complexes. 3 = transfer of metabolites from hemolymph (surrounding intestine, via vesicular cell-hemocyte couples and in sub-integumental hemolymphatic sinuses) to acini. 4, 5, 5a, 5b, 5d, 5e = lytic material resulting from gamete atresis (when this occurs) is incorporated into macrophagic hemocytes (4), or is expelled into the gonoducts and partially absorbed by the gonoduct epithelium (5). This material is also absorbed by macrophagous hemocytes within the gonoducts (5a = these may be expelled from the acini at the same time as the lytic debris). Any remaining lytic material is expelled through the gonopore and into the pallial cavity, where it may be lost to the external medium (5b), or directed toward the gonad integument (5d) or the mantle (M) epithelium (5e) by the circulation of the pallial fluid. 6, 7 = absorption of lytic material by the gonad epithelium and transfer to subjacent hemocytes (6), or by the mantle epithelium and transfer to subjacent hemocytes (7). (After Le Pennec et al. 1991).

Isochrysis galbana and *Chaetoceros muelleri* resulted in a higher gonadal index, a higher dry weight of spawned eggs, a greater concentration of acylglycerol in the gonad, and greater spawning synchrony compared to discontinuous (batch) feeding. Since the production of microalgal diets represents a major cost to commercial hatcheries, overfeeding of broodstock should be avoided. Paon and Kenchington (1995) found that unlike in wild populations, adductor muscles of *Placopecten magellanicus* conditioned in a hatchery did not decrease in weight while gonads were developing, suggesting that these animals were being given more food than they needed merely to complete gametogenesis. Similarly, Grant and Cranford (1989) found that *P. magellanicus* fed a diet of cultured phytoplankton had significantly greater somatic and gonad weights compared to scallops fed aged kelp powder or sediment diets, but that gonad index was not affected.

Cochard and Devauchelle (1993) found that scallops, *Pecten maximus*, originating from St. Brieuc were more difficult to artificially condition than scallops from Brest. Conditioning success (percentage of scallops spawning) varied between populations for differing conditions of photoperiod, food ration, and temperature (Devauchelle and Mingant 1991). These differences in response to conditioning between stocks of *P. maximus* suggest that there are genetic differences that could be commercially exploited.

6.5.2 Spawning

Once broodstock animals reach sexual maturity, synchronous and complete spawning of gametes is desired. For *Pecten ziczac*, thermal stimulation (rapid increase from 20 to 29°C) was found to be an effective method for inducing spawning in both sexes, but intragonadal injection of serotonin was effective only in inducing release of spermatozoa (Vélez et al. 1990). For maximum egg yield from *Chlamys asperima*, a combination of temperature induction (raising water temperature 4°C in 30 min) and serotonin injection was suggested (O'Connor and Heasman 1995). Injections of serotonin, dopamine and noradrenaline into gonads of *Argopecten purpuratus* induced the release of sperm only, but injection of a combination of dopamine and prostaglandin induced spawning of both ova and spermatozoa (Martínez et al. 1996). For *Argopecten ventricosus*, serotonin injections effectively induced males to spawn, and thermal stimulation combined with exposure to sexual products resulted in a 50% spawning rate of both sexes (Monsalvo-Spencer et al. 1997). Desrosiers and Dubé (1993) found that exposure to flowing seawater was 10 times more effective at inducing spawning of *Placopecten magellanicus* than serotonin injection.

6.5.3 Larval Growth and Survival

Larval growth and survival depends to a large extent on the nutritional content of ova, which in turn depends on broodstock conditioning history. Inadequate levels of polyunsaturated fatty acids such as 20:4 (n-6), 22:6 (n-3), and 20:1 (n-9) in developing eggs are detrimental to larval development (Le Pennec et al. 1998). In support of this, Navarro et al. (2000) found that greatest survival rates of larval *Argopecten purpuratus* were achieved when broodstock were fed microalgal diets supplemented with a lipid

emulsion containing essential fatty acids. Stocks of *Pecten maximus* conditioned and spawned in the laboratory produced larvae that performed similarly but exhibited differences in survival during and after metamorphosis (Cochard and Devauchelle 1993).

6.6 SUMMARY

6.6.1 Gametogenic Cycles

Gametogenic cycles in scallops include periods of inactivity (vegetative periods), cytoplasmic growth, vitellogenesis, spawning, and resorption of unspawned gametes. Several means of assessing gametogenesis in scallops exist, including visual observation of the gonad (both gross and microscopic examination of gonadal smears), gonad weights and indices, histology (including oocyte diameter and stereology), and indirect means (larval and spat abundances). The most complete definition of a gametogenic cycle would include both quantitative estimates of fecundity and qualitative assessment of gametogenesis.

Considerable variation exists in pectinid gametogenic cycles. Intra-specific variations in the timing of spawning periods and the amount of gametogenic material produced occur between years and sites (location and depth), probably due to variations in environmental conditions that influence the gametogenic process. Aspects of gametogenesis vary along geographic ranges either as the result of environmental or genetic variability. Inter-specific differences in reproductive cycles also exist; the relative influence of genetic and environmental factors is unclear.

6.6.2 Regulation of Gametogenesis

Gametogenesis in scallops is regulated internally by neurosecretions and age and externally by environmental factors (primarily food and temperature), which synchronise the cycle. Regulation of gametogenesis is ultimately under genetic influence. Thus the factors regulating gametogenesis may vary between species or even within a species at different locations, resulting in variation in gametogenic cycles.

The regulation of gametogenesis is most completely understood for the bay scallop, *Argopecten irradians*. Once a minimum age is attained, a change in neurosecretory cycle stage (perhaps invoked by increased temperature) occurs. Scallops then become responsive to environmental stimuli for either initiation or delay of gonad growth. If minimum threshold day length, food, and temperature criteria are met, growth of oocytes is initiated in conjunction with the transfer of nutrients from the digestive gland to the gonad. After a certain amount of gametogenic material is accumulated in the gonad, development of oocytes to maturation is independent of food supply, providing minimal temperatures are maintained. This transition is marked by another change in neurosecretory cycle stage and effectively removes the gametogenic process from an uncertain environmental food supply. Fecundity, or the amount of gametogenic material produced, is determined by food availability above minimum threshold levels.

Spawning of gametes appears to rely on a combination of exogenous and endogenous factors. Once a state of gametogenic maturity is reached (through environmental and neurosecretory control), a variety of environmental stimuli can initiate spawning. The most universal of these is temperature. A rapid change in temperature appears to be more important than an absolute temperature or the direction of change. There is no critical, species-specific temperature for spawning. Physical disturbance (wind, tides) also stimulates spawning, as does the presence of gametes of the opposite sex (ectocrines). The influence of lunar periodicity on spawning is apparently indirect, resulting from temperature changes associated with spring tides. The effects of salinity and day length, are poorly understood. Changes in dissolved oxygen and pH are not relevant in seawater. Neurosecretory products such as serotonin and dopamine appear to be important in the spawning process. These chemicals or similar ones, released into the water with the gametes stimulate spawning in other members of the population, helping to synchronise the spawning process. Duration of spawning is limited by temperature and food supply and a return of the neurosecretory cycle to the stage coinciding with the resting stage.

Year class success might depend to a large extent on spawning intensity and synchrony, which in turn depends on gametogenic synchrony within the population and the presence of an effective spawning stimulus. The timing of spawning with respect to conditions suitable for larval growth and survival undoubtedly also contributes to recruitment success.

6.6.3 Energy Metabolism

The study of reproductive energy metabolism is concerned with the ways in which energy acquired from food is ultimately incorporated into gametogenic material. In scallops, nutrient reserves are stored primarily in digestive gland and adductor muscle body components during periods of somatic growth when food is abundant. Carbohydrate (mainly adductor muscle glycogen) appears to be of primary importance, but lipid stored in the digestive gland and protein stored in the adductor muscle also play important roles. These reserves may subsequently be catabolised to support maintenance metabolism when food is scarce and/or the production of gametes, depending on the timing of gametogenesis in relation to seasonal food supply.

Barber (1984) and Barber and Blake (1981, 1983, 1985a, 1985b) defined the gametogenic energy metabolism of *Argopecten irradians concentricus*. A period of growth and energy storage in which the adductor muscle increases in size and glycogen level occurs in the spring when food is abundant, prior to the initiation of gametogenesis. Metabolism is supported primarily by digestive gland lipid, which is declining in level at this time. Early in the gametogenic cycle maximum O/NH_3 and CO_2/O_2 (RQ) ratios indicate a shift to carbohydrate as the primary respiratory substrate, as the adductor muscle reaches maximal weight and its glycogen reserves begin to be utilised. As these glycogen stores are depleted in conjunction with gamete development, the adductor muscle decreases in weight and protein content. Gametes are mature by the end of the summer, as evidenced by maximum gonad weight and mean oöcyte diameter. Metabolism becomes primarily protein based as the adductor muscle reserves continue to

be catabolised. After spawning commences in the fall (when food energy is less available), energy reserves are depleted and scallop physiological condition is poor, as indicated by rapid carbon turnover and increasing senescence. This cycle of energy storage and utilisation is an integral part of the reproductive process, acting as a buffer between the regulating factors and the actual production of gametes. The energy cycle itself is undoubtedly controlled by neuroendocrine and environmental factors but is critical to reproductive success in that it provides the energy and material required for gamete synthesis.

Several mechanisms for the transfer of energy to developing oocytes have been proposed. These include: 1) direct transfer (via the hemolymph) of fatty acids from the digestive gland to developing ova; 2) the conversion of carbohydrate (stored in the adductor muscle) to fatty acids which are incorporated into developing ova; 3) the breakdown of protein (primarily adductor muscle tissue) to support energetic demands after other reserves are exhausted; 4) the recycling of energy from oocyte atresis; and, 5) intestinal loop transfer.

6.6.4 Applications to Aquaculture

Compared to oysters, clams, and mussels, the commercial culture of scallops is relatively new. A greater understanding of the factors regulating gametogenesis and spawning of scallops will lead to a more consistent supply of seed organisms (Devauchelle and Mingant 1991). Like other bivalves, scallops can be conditioned out of season with a microalgal diet, although more research is needed in order to optimise specific dietary requirements and delivery systems. This will lead to improvements in conditioning time and subsequent health of larvae. Once scallops are fully ripe, spawning can be induced using thermal or mechanical stimulation, injection of serotonin, exposure to sexual products, or some combination.

Chapter 7

Physiology: Energy Acquisition and Utilisation

Bruce A. MacDonald, V. Monica Bricelj and Sandra E. Shumway

7.1 INTRODUCTION

This chapter builds on a previous review of scallop physiology by Bricelj and Shumway (1991) included in an earlier edition of this text. The physiology of larval pectinids is not included, as the primary focus of this chapter is on post-settlement stages, juveniles and adults. Aspects related to nutrition (nutritional requirements of pectinids and substrate utilisation) and reproductive physiology are also excluded from this chapter. New, updated information is provided in areas that have received increasing attention since the publication of the first chapter, in particular the effects of flow, suspended sediments and of harmful algal blooms on scallop physiology. Readers are also referred to a comprehensive recent review of scallops in Iberoamerica, which includes several chapters on ecophysiology of scallops from that region (Maeda-Martínez 2002).

7.2 ENERGY ACQUISITION

7.2.1 Food Sources

Scallops are sublittoral, epifaunal, active suspension-feeding bivalves, which rely on suspended detrital material and phytoplankton as their food source. It has been suggested, however, that adult scallops are uniquely capable of exploiting food particles associated with surface sediments resuspended by their “shell clapping” activity (Davis and Marshall 1961). This ability has been demonstrated in the laboratory (Davis and Marshall 1961), but its significance in the natural environment is not known. Grant and Cranford (1989, 1991) and Cranford and Grant (1991) found that detrital diets alone, such as fresh and aged macroalgal detritus from the kelp *Laminaria longicruris*, or resuspended sediments containing benthic microalgae, were inadequate to support growth of adult *Placopecten magellanicus* under laboratory conditions. Only phytoplankton diets (*Isochrysis galbana* or *Chaetoceros gracilis*) fed at weight rations comparable to the detrital diets, sustained tissue and gonad growth in this species. Scope for growth (SFG) estimates derived from physiological data indicated that the phytoplankton diets yielded a positive SFG for both carbon and nitrogen, whereas aged kelp, a carbon-rich food source, yielded a positive (although relatively low) SFG for carbon but negative SFG for nitrogen (Grant and Cranford 1990). Aged kelp was readily absorbed (carbon absorption efficiency, at 87%, was comparable to that determined for the diatom diet) but resulted in markedly reduced

clearance rates and nitrogen ingestion rates compared to algal diets. Fresh kelp resulted in lower and highly variable absorption efficiencies (0 to 60%) compared to aged kelp. Lack of growth of sea scallops on kelp detritus alone was thus attributed primarily to nitrogen deficiency and contrasts with findings in the mussel, *Aulacomya ater*, which can maintain a positive energy balance on a kelp diet (Stuart 1982). Studies using ^{15}N as a tracer (Alber et al. 1988) indicate that nitrogen released as dissolved organic matter by senescing macrophytes (*Enteromorpha*, *Gracilaria*, *Fucus* and *Spartina*) can be aggregated into amorphous particulate matter and ingested and assimilated by bay scallops, *Argopecten irradians*, under laboratory conditions. Bay scallops were capable of absorbing nitrogen and organic material from aggregates or flocs, although less efficiently than they were able to assimilate phytoplankton (Alber and Valiela 1996). These authors suggested that organic aggregates, or flocs, could potentially represent an important and nutritious food source for suspension-feeding bivalves. Furthermore, studies on the activity of digestive enzymes show that bivalves, including scallops, have the capacity to digest macroalgal detritus (Wojtowicz 1972; Brock et al. 1986). Overall, the above studies thus indicate that macrophyte detritus has the potential to supplement phytoplankton as a food source in the natural environment and may help to meet energy demands of scallops when the phytoplankton supply is low.

At least three studies based on gut content analysis (Davis and Marshall 1961; Vernet 1977 and Shumway et al. 1987) have independently shown that benthic and/or tychopelagic algae are an important component of the scallops' diet. Davis and Marshall (1961) found that benthic diatoms (e.g., *Melosira*, *Licomophora*, *Cocconeis*) were more abundant than planktonic diatoms in gut contents of *Argopecten irradians*. They also reported that the numerical abundance of live benthic algae in water samples increased with increasing proximity to the sediment surface (from 32% 30 cm above the bottom to 80% approximately 0.5 cm from the bottom). Shumway et al. (1987) compared gut contents of shallow (20 m) and deep water (180 m) populations of *Placopecten magellanicus* in the Gulf of Maine. Again, benthic algae such as *Melosira*, *Navicula* and *Pleurosigma* were found to outnumber pelagic forms in gut contents of the deep water population. Interestingly, both resting cysts of the toxic dinoflagellate *Protogonyaulax* (= *Alexandrium*) *tamarensis*, and *Dinophysis* cells, implicated in outbreaks of paralytic shellfish poisoning (PSP) and diarrhetic shellfish poisoning (DSP) respectively, were abundant in gut contents. Vernet (1977) determined the seasonal algal composition of gut contents of the Patagonian scallop, *Chlamys tehuelpa*, as well as that of bottom sediments and plankton samples collected immediately above scallop beds in the Gulf of San José, Argentina. Benthic algae such as *Synedra investens*, *Melosira sulcata*, *Grammatophora marina* and *Navicula* spp., were dominant in gut contents throughout most of the year (Fig. 7.1). Planktonic diatoms such as *Chaetoceros* and *Thalassiosira* species, which were the dominant component of the spring phytoplankton bloom, were rarely present in gut contents. Furthermore, benthic algae that attach to sand grains by gelatinous stalks, such as *Glyphodesmia distans*, *Glyphodesmia* spp. and *Plagiogramma interruptus*, and were abundant in sediments, were absent from gut contents, presumably because they are not readily resuspended. It is interesting to note that scallop eggs were relatively abundant in stomach contents during the spawning season.

Figure 7.1. Seasonal changes in source of the diet (% numerical abundance of planktonic and benthic microalgae) as determined from stomach content analysis in the Patagonian scallop *Chlamys tehuatla* (1975 cohort) (modified from Vernet 1977).

Adult scallops are capable of ingesting relatively large particles and this ability has been related to the absence of mechanisms for sorting particles on the basis of size by the gills of Pectinidae (Beninger et al. 1988). Particles up to 950 μm were described in the gut contents of *Patinopecten yessoensis* (Mikulich and Tsikhon-Lukamina 1981). Gut contents of *P. magellanicus* ranged from 10 to 350 μm (Shumway et al. 1987). By comparing the algal composition and size spectra of the plankton with stomach contents of *Chlamys tehuelpa*, Vernet (1977) found, however, that this scallop showed negative selection for particles exceeding 100 μm .

Changes in diet may be associated with major shifts in habitat of scallop species that move from an above-bottom, byssally attached juvenile stage to a free-living existence on the bottom as adults. Such changes have not yet been investigated.

7.2.2 Feeding Currents and Mechanisms of Particle Capture

Scallops are non-siphonate, ciliary suspension-feeders, which exhibit no fusion of the mantle edge. Water enters the mantle cavity along the ventral and anterior edge, and exits through the posterior exhalent opening (Hartnoll 1967). In *Argopecten irradians* this aperture is about five times larger than the anterior inhalent opening (Winter and Hamilton 1985). Scallops preferentially orient themselves by facing directly into the current (exhalent opening facing away from the direction of the flow) (Hartnoll 1967; Caddy 1968; Mathers 1976; Grant et al. 1992). Adults possess a plicate, heterorhabdic gill in which ordinary filaments and principal filaments form the crests and grooves respectively of the plicae.

Bivalves have been suggested to capture particles by direct interception with the ctenidial filament and transport the particles along the frontal surface of the filament by mucociliary processes (Ward et al. 1998a; See section below on "Particle retention efficiency" for alternative views). This mechanism for particle capture is consistent with theories of hydrosol filtration observed for many different groups of aquatic suspension-feeders (Shimeta and Jumars 1991). The low angle of particle approach to the filament increases the probability of encounter with frontal cilia and the vertical flow set up by the beating of the laterofrontal cilia or cirri reduces flow through the interfilamentary spaces and redirects particles to the frontal surface of the filament (Ward et al. 1998a). According to these authors, these two processes affecting flow patterns promote the retention of particles on the frontal surface by increasing the encounter efficiency with the frontal cilia.

While the mechanism of particle capture itself is likely to be similar for most species of bivalves, the velocity and sites of particle transport on the gill and the efficiency of retention vary among species including pectinids. Oysters (*Crassostrea virginica* and *Ostrea* sp.) and mussels (*Geukensia demissa*, *Mytilus edulis* and *Modiolus modiolus*) have well developed ventral ciliated grooves where particles are incorporated into a cohesive mucus string and transported at relatively low velocities anteriorly toward the labial palps (Ward 1996). In *C. virginica* the opposing surfaces of the ridged labial palps reduce the cohesiveness of the mucus strings and disperse entrapped particles for ingestion whereas

in *M. edulis* the ridged surface of one palp and the action of the ciliated dorsal margin disperse particles (Ward 1996).

The scallop, *P. magellanicus*, and mussel, *Arca zebra*, however, lack ventral grooves and only small mucus aggregations or strings accumulate on the ventral margins which could be transported to the labial palps for rejection as pseudofeces (Ward 1996). Particles destined for ingestion by *P. magellanicus* are suspended in a slurry and transported at high velocities in the dorsal tracts rather than in a mucus-bound string along the ventral margin (Ward 1996).

7.2.3 Particle Retention Efficiency

The amount of food available to suspension-feeding bivalves is a function of the volume of water transported across the gills (pumping rate) as well as the efficiency with which particles are retained by the gill. Most juvenile and adult suspension-feeding bivalves are able to retain particles above 3–4 μm with 100% efficiency, and retention efficiency decreases with decreasing particle size (to between 35 to 90% for 2 μm particles) (Møhlenberg and Riisgård 1978; Riisgård 1988). This pattern is consistent with capture mechanisms other than sieving proposed by modern filtration theory (Rubenstein and Koehl 1977; Jørgensen 1981, 1983). In contrast, the limit for effective retention of particles in members of the Pectinidae studied to date, [including *Pecten opercularis*, *P. septemradiatus* (Møhlenberg and Riisgård 1978), *Chlamys opercularis* (Vahl 1972) and *C. islandica* (Vahl 1973a) and *Argopecten irradians concentricus* (Palmer and Williams 1980; Riisgård 1988)], is about 5–7 μm (Fig. 7.2). Free bacterioplankton, typically ranging in size from 0.3 to 1 μm , is therefore not available as a food source for pectinids unless bound in aggregates. The retention pattern for particles below 5–7 μm , however, varies somewhat between species. For example, *C. islandica* is more efficient in capturing small particles than *C. opercularis* (retention efficiencies for 2 μm = ca. 27 and 5%, respectively (Vahl 1973a).

It should be pointed out that retention efficiencies are generally determined using electronic particle counters. Jørgensen et al. (1984) found that these instruments tend to somewhat overestimate retention efficiencies of small particles (<2 μm in diameter) generally determined with a 50 μm aperture tube. This is partly attributed to interference by conductive colloidal particles in seawater, and electrical noise at the lower limit of resolution of the particle counter, although recent multisizers are capable of increased resolution at small sizes.

The influence of particle concentration on retention efficiency in bivalves is not fully resolved. Palmer and Williams (1980) found that *Argopecten irradians concentricus* were significantly more efficient in retaining small particles (<3.4 μm) at high algal concentrations that induce pseudofeces production (6.1 mg wet weight L^{-1}) than at low concentrations below the threshold for pseudofeces production (0.9 mg L^{-1}), whereas an inverse effect was observed in the oyster *Crassostrea virginica*. The addition of a higher concentration of bentonite clay to an algal suspension caused a reduction in the retention efficiency of small particles by *Placopecten magellanicus* (Cranford and Gordon 1992).

Figure 7.2. Retention efficiency (%) as a function of particle size in several pectinid species (redrawn from references cited in the text) compared to that of a bivalve with well developed eulaterofrontal cirri, e.g., the softshell clam, *Mya arenaria* (line fitted to the data from Møhlenberg and Riisgård 1978). ^aRiisgård 1988; ^bPalmer and Williams 1980, retention measured at low algal concentrations (0.9 mg wet weight L⁻¹).

Bivalves possess three types of ciliary tracts in their gill filaments: lateral (current producing), frontal (particle carrying), and laterofrontal tracts believed to play a role in particle retention (Owen and McCrae 1976). Although the mechanism of particle retention by the bivalve gill is not fully understood (see below) retention efficiency of small, bacteria-sized particles has been correlated with the development or structural complexity of laterofrontal tracts in both marine and freshwater bivalves (McHenerly and Birbeck 1985; Silverman et al. 1997). Thus the poor retentiveness for small particles of the pectinid gill has been ascribed to the poor development of laterofrontal ciliary tracts in this group of bivalves (Owen and McCrae 1976; Møhlenberg and Riisgård 1978). The laterofrontal tracts consist only of small, simple pro-laterofrontal cilia, and lack the large, compound eulaterofrontal cirri characteristic of mussels (Owen and McCrae 1976). Thus, these authors suggest that the poorly developed laterofrontal cilia of pectinids play no role in particle retention. They suggest that, at low to moderate particle loads, the form of the plcae and U-shaped nature of principal filaments all combine to create a region of low pressure which tends to attract particles into the gutters formed by principal filaments.

Laterofrontal ciliary tracts, located across the entrance to interfilamentary spaces, are attributed a role in particle retention in numerous studies involving mussels, which are

characterised by large, complex cirri. However, the exact mechanism of particle retention by laterofrontal cilia or cirri has remained controversial, ranging from their action as mechanical filters or sieves (direct mechanical interception) (Dral 1967) to a hydromechanical role in capture (Jørgensen 1990), or a combination of other multiple mechanisms (Ward et al. 1998a). A mechanical role of the cirri is supported by differential particle capture in freshwater bivalves with cirri of different sizes (Silverman et al. 1997). Capture via a hydrodynamic mechanism is presumably achieved by influencing the steepness and height of velocity gradients in the boundary zone between currents entering the gill interfilamentary space, and surface currents along the frontal surface of gill filaments (Jørgensen 1981). Jørgensen's velocity gradient hypothesis, developed for the mytilid filibranch gill, predicts that the critical size for efficient particle retention should be larger in bivalves (such as pectinids) with reduced laterofrontal ciliary tracts. Ward et al. (1998a) argued that low Reynolds numbers preclude a mechanical sieving role of laterofrontal cilia/cirri (also reviewed by Jørgensen 1996), and that hydrodynamic entrainment may occur on principal but not ordinary filaments. Based on endoscopic observations they concluded that particle capture occurs by direct interception at the frontal surface of ordinary gill filaments and indeed does not require the presence of laterofrontal tracts. They suggest that the main role of the laterofrontal tracts is to increase the probability of encounter of particles with the frontal surface of gill filaments, by inducing lateral flows that reduce particle loss through the interfilamentary spaces. However, the pectinid gill was not represented in their study and these findings remain controversial.

Despite the controversy over the mechanism of particle capture as determined by *in vitro* methods using isolated gill filament preparations or *in vivo* methods applied to intact animals (e.g., confocal microscopy and video endoscopy respectively), each of which has inherent limitations [see Comments by various authors in *Limnol. Oceanogr.* 45(5), 2000], several recent studies of mytilids may support the role of the laterofrontal cirri in capturing particles and directing them to the frontal surface of gill filaments for subsequent transport (Riisgård et al. 1996; Silverman et al. 1996, 1999, 2000). Using confocal laser scanning microscopy and high-speed video recordings of isolated gill sections, Silverman et al. (1999) concluded that the movement of cirri in *Mytilus edulis* was essential for successful capture of small, bacterial-sized (1 μm) particles although they could not discriminate between mechanical and hydromechanical interception. This was further supported by the fact that mussels treated with serotonin concentrations that stopped the beat of laterofrontal cirri, but not that of frontal or lateral cilia on the gill filaments, showed a 90% reduction in the rate of removal of bacteria from seawater relative to untreated controls.

Post-settlement scallops undergo major changes in the anatomy of feeding organs, especially the gill, during early development. Ontogeny recapitulates phylogeny as the postlarval gill experiences a gradual transition from a homorhabdic condition, with a single, non-plicate inner demibranch, to a heterorhabdic, plicate, reflected gill consisting of both inner and outer demibranchs (Kingzett 1993; Beninger et al. 1994; Veniot et al. 2003), characteristic of adult scallops (Beninger and Le Pennec, Chapter 3). Lateral and frontal cilia are well developed early on in the gills or postlarval stages, but the latero-

frontal cilia are absent in these early stages (Veniot et al. 2003). It is expected that such profound anatomical changes are associated with differences in gill function: suspension-feeding appears to be relatively ineffective in postlarvae prior to reflection of the demibranchs, as evidenced in *Patinopecten yessoensis* by very low clearance rates at sizes <600 µm in shell height (SH) (Kingzett 1993). Yet little is known about the retention efficiency of the postlarval gill in any bivalve species.

From the gut contents of *P. yessoensis* offered suspensions of fluorescent polystyrene beads either 2, 6, 9, 23 or 55 µm in diameter, Kingzett (1993) determined that postlarvae ~300 and 1,000 µm SH were unable to ingest beads of the two largest bead sizes tested, suggesting that the upper limit for capture/ingestion of particles is approximately 20 µm. However, at 300 µm SH scallops were able to ingest approximately equal numbers of 2 and 6 µm beads when offered at the same concentration. Thus, retention efficiency differs between early postlarvae and adult scallops. Firstly, postlarvae appear to have a lower maximum size limit for particle retention, and secondly, despite the absence of laterofrontal cilia on gill filaments, postlarvae appear to be capable of effectively capturing small 2 µm particles. One of the limitations in Kingzett's study is that the different bead sizes were not fed to the animals simultaneously, thus precluding accurate measures of retention efficiency. It is important to note that measures of gut content do not allow differentiation of the particle retention/capture per se, but reflect the integration of feeding processes leading to ingestion: retention-transport-selection-ingestion. Confirmation of effective retention of small (1–2 µm) particles by the postlarval scallop gill, which lacks laterofrontal cilia, may challenge previous suggestions that these cilia are prerequisite for small-particle capture in suspension-feeding bivalves (Riisgård et al. 1996; Silverman et al. 1996, 1999, 2000). However, it is difficult to make direct comparisons between the mechanics of particle capture of early scallop postlarvae and adults, as the morphology of the gills differs markedly between the two stages.

7.2.4 Feeding Rates

The allometric relationship between clearance rate and body size (tissue dry weight) for several pectinid species is shown in Table 7.1. The weight exponent is variable, ranging from 0.58 to 0.94, with a mean of 0.7, which is within the range published for other bivalves (Bayne and Newell 1983). The allometric exponent was found to be considerably higher (mean = 0.92) in larvae and juveniles (up to ~10 mm) of the bay scallop, *Argopecten irradians concentricus* (Lu and Blake 1997) than that reported for adult pectinids. The relationship between clearance rate (CR, in µL hr⁻¹) and total body ash-free dry weight (AFDW, in mg) in these early development stages at 25°C and a near-optimum food concentration of 20 cells T-ISO µL⁻¹ was described by the equation:

$$CR = 56.565 \cdot W^{0.931}, \text{ or when expressed in terms of shell height (H, in mm) as:}$$

$$CR = 1.051 \cdot H^{2.479} \quad (1)$$

Table 7.1

Parameters of the allometric relationship between clearance rate (CR; L h⁻¹) and tissue dry weight (W; g) according to the equation $CR = aW^b$, in several pectinid species.

² Calculated by Winter (1978).

Weight-normalised clearance rates (volume of water cleared of particles per unit time by an animal of standard tissue weight) of various pectinid species are shown in Table 7.2. It is generally difficult to make meaningful interspecies comparisons of feeding rates derived from studies differing in methodology and experimental conditions. This is especially true given that clearance rates are extremely sensitive to changes in food quality and quantity. Declining salinities (between 27 and 18 ppt) have also been shown to markedly reduce clearance rates in the Chilean scallop *Argopecten purpuratus* (Navarro and González 1998). Physiological rates of scallops are generally very susceptible to the negative effects of low salinities, as they are unable to maintain prolonged valve closure and thus cannot effectively isolate themselves from the environment. Interspecific comparisons in feeding rates are therefore best carried out from studies, which employ identical experimental protocols on a wide variety of bivalve species. For example, Meyhöfer (1985) found that weight-standardised pumping rates were highest for two filibranch species, the scallop *Chlamys hastata* (0.145 L h⁻¹) and mussel *Mytilus californianus* (0.133 L h⁻¹), followed by *Clinocardium nuttallii* (0.051 L h⁻¹) and finally by *Macoma nasuta* (0.0014 L h⁻¹), a deposit-feeder capable of facultative suspension-feeding. When *Mya arenaria* and *Placopecten magellanicus* were simultaneously exposed to various concentrations of particles scallops displayed higher weight specific

clearance rates than clams, especially at concentrations less than 7.0 mg L^{-1} (Bacon et al. 1998). Møhlenberg and Riisgård (1979) compared feeding rates of thirteen bivalve species and reported clearance rates considerably higher than those from previous studies. Weight-standardised clearance rates of the two scallops, *Pecten furtivus* and *Pecten (Chlamys) opercularis*, based on only three measurements (Table 7.2), were comparable only to those of *Mytilus edulis* but were generally two to five times higher than those of other bivalves included in the study.

Feeding rates in bivalves, including pectinids, have also been shown to be influenced by chemical compounds such as metabolites extracted from cultured microalgae. There are several examples of bivalves exhibiting chemosensory abilities, with some dissolved phytoplankton metabolites typically producing inhibitory feeding responses as in the case of the blue mussel *Mytilus edulis* (Ward and Targett 1989). Stimulatory responses are much rarer but have been observed for clearance and ingestion rates in *Placopecten magellanicus* when scallops were exposed to metabolites from the diatom *Chaetoceros muelleri* Lemmermann (Ward et al. 1992). A microalgal diet supplemented with a lipid emulsion also had a stimulatory effect on clearance rates in *Argopecten purpuratus* (Navarro et al. 2000). A better understanding of the capability of bivalves to detect and respond to chemical cues has interesting implications for research on artificial diets possibly making them more palatable and more readily ingested by the bivalves.

It has recently been discovered that 6–15 μm ciliated and non-ciliated epithelial cells can be released from the pallial cavity of sea scallops *Placopecten magellanicus* (MacDonald et al. 1995; Potter et al. 1997). Release of a large number of these cells may lead to an estimate of negative clearance rates, i.e., higher concentrations of suspended particles after exposure to the bivalve than in the original suspension. Exfoliation of these cells has also been observed, although not quantified, for the blue mussel *Mytilus edulis* and the eastern oyster *Crassostrea virginica* (MacDonald, pers. obs.) and *Mercenaria mercenaria* (Bricelj, pers. obs.). Exfoliation of small numbers of cells may be a consequence of cellular turnover and normal physiological function. However, environmental stressors, such as unseasonably elevated water temperatures are known to increase the rate of cell release to the point that tissue damage results (Potter et al. 1997). It is not known what other stressors may cause increased exfoliation rates in bivalves or the short- and long-term consequences that any potential damage will have on the efficiency of particle retention and transport on the gill.

7.2.5 Clearance Rate in Relation to Food Concentration

When exposed to increasing suspended particulate loads, suspension-feeding bivalves are able to control the total amount of material ingested by: a) reducing the time spent pumping (discontinuous feeding behaviour), b) reducing their clearance rates, and/or c) increasing the amount of material rejected in pseudofeces (Foster-Smith 1975a, b; 1976). Palmer (1980) characterised the bay scallop, *Argopecten irradians*, as a continuous feeder, that showed no rhythmic cycles in clearance rates in response to tidal cycles or photoperiod. In contrast, Mathers (1976) suggested that the feeding activity of *Pecten maximus* was cyclical in response to changes in tidal flow. He indicated, however, that

this was caused by strong reversible tidal currents and was probably not an endogenous feature of the scallop's feeding behaviour. Existing evidence, although limited to a few pectinid species (see below), suggests that scallops primarily regulate ingestion and compensate for short-term changes in food supply through fluctuations in clearance rate (mechanism b).

A strong inverse, linear relationship between clearance rate and algal concentration has been described for adult bay scallop *Argopecten irradians concentricus* (Palmer 1980; Fig. 7.3A). Clearance rates are reduced by 95% over the concentration range 0.94 to 9.4 mg dry wt. L⁻¹ (1.23 to 12.3 × 10⁶ μm³). Therefore, above a threshold concentration of ca. 2 mg dry weight L⁻¹, algal ingestion rate becomes independent of concentration (Fig. 7.3B). Similarly, clearance rates of juvenile *A. i. irradians* were found to decline by 85% with a 10-fold increase in the concentration of *Thalassiosira weissflogii* (1.2 to 12 cells μL⁻¹ = 0.83 to 8.3 × 10⁶ μm³ mL⁻¹) (Kuenstner 1988). Cahalan et al. (1989) reported a lower reduction (56%) for juvenile bay scallops exposed to concentrations between 7.5 and 68 cells μL⁻¹ (0.25 to 2.28 × 10⁶ μm³ mL⁻¹) of *Isochrysis galbana*, an alga that is incompletely retained by the pectinid gill. Lu and Blake (1997) found that clearance rates of juvenile bay scallops, *A. i. concentricus* (~0.6 to 9.8 mm in shell height) declined exponentially with increasing algal concentration ranging between 5 and 50 *I. galbana* cells μL⁻¹ (Fig. 7.3C). Ingestion rate, however, increased with increasing cell concentration, and approached an asymptote or maximum ingestive capacity at ~ 50 cells μL⁻¹ (Fig. 7.3D). It is interesting to note that larvae reached this asymptote at a lower cell density (~ 20 cells μL⁻¹) than larger juveniles, suggesting that the latter are better able to handle dense algal assemblages than larval stages. An optimum cell density of 20 cells μL⁻¹ was established for growth of juveniles of this species, as higher concentrations (up to 50 cells μL⁻¹) did not significantly increase growth rates (Lu and Blake 1996). Similarly, growth rates in shell height and tissue weight of juvenile *Nodipecten subnodosus* (lion's paw scallop) were maximised at the lowest algal concentration tested (33 T-ISO cells μL⁻¹). Growth was comparable at 33 and 66 T-ISO cells μL⁻¹, and declined at 100 cells μL⁻¹ (García-Esquivel et al. 2000).

Clearance rates for *Placopecten magellanicus* and *Mya arenaria* both significantly declined as concentration and organic content of microalgae and silica mixtures increased between 1 and 14 mg L⁻¹ (Bacon et al. 1998). However, other studies on *P. magellanicus* have reported clearance rates to be independent of particle concentration between 1–15 mg L⁻¹ and this may be related to the type of particles used in the individual studies (Cranford and Grant 1990; Cranford and Gordon 1992; MacDonald and Ward 1994; Cranford et al. 1998). Several authors have emphasised the potential interactions between seston concentration and flow velocities on the feeding response of scallops (Wildish et al. 1992; Wildish and Saulnier 1993; Pilditch and Grant 1999a). How scallops respond to changes in particle concentration may not only depend on variations in flow speeds, but also on whether or not the flow is increasing or decreasing in velocity (Pilditch and Grant 1999a). These authors observed a decline in scallop clearance rates when phytoplankton concentration increased and flow velocities were increasing but found clearance rates to be independent of concentration, albeit reduced by 50%, when flow velocities were decreasing. They concluded that the scallop's short-term (hours) feeding history may be

Figure 7.3. *Argopecten irradians concentricus* adults. Relationship between algal concentration ($\text{mg dry weight L}^{-1}$) and clearance rate (A) and amount of algae cleared (B). Each point represents the mean value for one experiment - that is for 5 to 32 hourly measurements; algae used were *Dunaliella tertiolecta* (x) or *Thalassiosira pseudonana* (•) (from Palmer 1980). *Argopecten irradians concentricus* juveniles. Relative clearance rate (C) and algal ingestion rate (D) as a % of the maximum of bay scallops ranging from 1.1 to 9.8 mm shell height at 25°C (calculated from data in Lu and Blake 1997). Data fitted to exponential (C) and logarithmic functions (D).

influential in determining its response to variations in the food supply and that concentration was the primary determinant of scallop clearance rate over a range of fluxes (Pilditch and Grant 1999a). See the section 7.2.10 on “Effects of flow on feeding and growth” for a more detailed discussion on the effects of flow on feeding activity.

Hawkins et al. (2001) have also emphasised the importance of the amount of suspended material in regulating clearance rates in the scallop *Chlamys farreri*, in particular the volume and composition of the seston. They found that clearance rate varied in a unimodal relation with short-term changes in seston abundance and was primarily dependent upon seston availability in terms of total volume rather than any gravimetric estimate of mass. They suggested morphometric limits to feeding behaviour, most likely constraints within the digestive system rather than on the gills. There is also an interaction between seston volume and seston quality with 58% of the variance in clearance explained by particle volume and chlorophyll concentration combined, in contrast to only 47% for seston volume alone (Hawkins et al. 2001). These authors observed over an order of magnitude variation in clearance rates and concluded that this potential for feeding adjustment would be of greatest physiological and ecological importance at low food availabilities because it would have proportionally more impact on net energy balance.

7.2.6 Influence of Temperature on Feeding Rates

The effect of temperature on feeding activity has been investigated in few pectinid species. Clearance rates of *Argopecten irradians concentricus* were independent of temperature between 10 and 26°C, but were markedly depressed at 5°C (Fig. 7.4B; Kirby-Smith 1970). Since the increase in metabolic expenditure between 10 and 26°C is not offset by a parallel increase in feeding activity, the irrigation efficiency (litres pumped per mL of O₂ consumed) decreases rapidly with increasing temperature above 10°C (Fig. 7.4A). Irrigation efficiency is generally assumed to be inversely related to the maintenance food requirement (that at which growth = 0) (Newell and Kjøfoed 1977). Therefore, it is expected that bay scallops will sustain a maximum energetic gain from the environment between 10 and 20°C, and that they will be severely stressed, and exhibit rapid weight loss, under suboptimal conditions of poor food supply and high temperature. Such conditions might arise due to an increase in water temperatures during winter (caused by thermal pollution) without a concomitant increase in food levels. The scallops' dependence on higher food levels at high temperatures is exemplified by the finding that growth rate of juveniles at lower temperatures (10 to 16°C) is independent of chlorophyll-*a* levels within the range of naturally occurring concentrations (0.5 to 5.5 µg L⁻¹), but becomes increasingly correlated with chlorophyll levels at higher temperatures (22 to 28°C) (Kirby-Smith 1970; Kirby-Smith and Barber 1974).

In contrast to the above findings for adults, clearance rate of juvenile *A. i. concentricus* was an increasing function of temperature between 10 and 30°C (Fig. 7.4D), which approximates the temperature range of this species in its natural habitat in Florida, USA (~12 to 32.5°C) (Lu and Blake 1997). Thus juveniles may be better able to exploit

Figure 7.4. *Argopecten irradians concentricus* adults. Mean oxygen uptake (A) and clearance rate (B) of a standard animal 20 g in wet tissue weight (calculated from data by Kirby-Smith (1970; Tables VII and VIII for scallops fed *Nitzschia* sp.; vertical bars = standard errors). *Argopecten irradians concentricus* juveniles. C. Weight-specific mean oxygen uptake ($\pm$ SD) vs. temperature of juveniles 3.5 to 5 mm in shell height (plotted from Lu et al. 1999). D. Clearance rate vs. temperature of 5 mm juveniles at different *Isochrysis galabana* cell concentrations (plotted from Table 3 in Lu and Blake 1997).

higher temperatures when these coincide with an abundant food supply than adults. As in adults, oxygen uptake in juveniles increased with increasing temperature (Fig. 7.4C).

In *Chlamys opercularis* the response of clearance rates to temperature is similar to that of adult bay scallops. Feeding rates are independent of acclimation temperature between 10 and 20°C, but drop markedly at 5°C (Q_{10} from 5 to 10°C = 3.87; Q_{10} from 10 to 20°C = 1.83; McLusky 1973). Unlike bay scallops, however, oxygen uptake remains

constant between 10 and 20°C, allowing conservation of energy at higher temperatures. This strategy is similar to that displayed by *Mytilus edulis* (Bayne et al. 1976). In *Placopecten magellanicus* from Newfoundland, clearance rates were significantly correlated with ambient temperature in both shallow (10 m) and deep water (31 m) populations between 0 and 12°C. In the latter, clearance rates were also correlated with food availability (energy content of seston) (MacDonald and Thompson 1986). In juveniles of the subtropical scallop, *Argopecten ventricosus-circularis*, routine oxygen consumption rate increased steadily between 12 and 28°C, whereas clearance rate and algal ingestion rate were maximised between 19 and 20°C, and declined above and below this temperature range (Sicard et al. 1999). This physiological optimum temperature range was confirmed by determining that shell growth was also maximised at 19–22°C. Furthermore, scope for activity, defined as the difference between routine (active) VO_2 and standard (basal) VO_2 determined for fed and starved animals respectively, was also maximised at 19°C. This illustrates that physiological rates can be very useful in predicting optimum ranges of environmental factors for growth.

Marine suspension-feeders inhabiting coastal waters typically pump 15 L or more of water per equivalent mL of O_2 consumed (Jørgensen 1975). A mean irrigation efficiency or convection requirement of 17 (8 to 25) was reported for *Pecten latiauratus* (Jørgensen 1960), and values ranging from 15 (at 5°C) and 39 (at 20°C) were found for *Chlamys opercularis* acclimated to laboratory conditions (McLusky 1973). A considerably higher mean value of 79 (range = 63–97) was reported for the same species by Vahl (1972). A maximum irrigation efficiency of 8.8 L mL^{-1} O_2 was obtained for juvenile *A. ventricosus-circularis* at 19°C (Sicard et al. 1999).

7.2.7 Pseudofeces Production, Pre- and Post-ingestive Particle Selection

Pseudofeces production has been shown to be an important pre-ingestive mechanism because it facilitates the process of particle selection whereby less nutritious particles may be rejected and the quality of the ingested material improved proportionately. The labial palps are currently believed to be the principal site of pre-ingestive particle selection via pseudofeces production in bivalves, although the evidence remains inconclusive. Their role in particle selection is supported by Kiørboe and Møhlenberg's (1981) finding that selection efficiency is positively correlated with a relative index of palp size (ratio of palp area to clearance rate) and other indirect evidence. Direct endoscopic observations of the pectinid palps to confirm their role in particle selection have so far proved elusive due to their extreme sensitivity and obstruction by the complex, arborescent lips (Beninger et al. 1992). Morphological evidence of their role in selection, e.g., presence of sensory structures on the ridged surface, was found to be lacking in both *P. magellanicus* and *Chlamys varia* (Beninger et al. 1990). Selective rejection of particles may also occur on the bivalve heterorhabdic gill, e.g., via rejection of material from the ventral gill margin [most notably in oysters, *Crassostrea virginica* (Ward et al. 1997, 1998b)]. Endoscopic observations indicate that even in pectinids, which lack a ventral groove, particles bound in mucus may move ventrally along ordinary filaments, and break off as pseudofeces as they move anteriorly (Beninger et al. 1992). This type of transport is only observed at

high particle concentrations or when the scallop's ingestive capacity is overloaded. Pseudofeces in adult scallops are ejected from the pallial cavity via valve clapping. Particle selection through the production of pseudofeces has been demonstrated in studies on feeding activity using laboratory diets and cultured algae mixed with sediments and assemblages of natural particles found in the environment (Kjørboe et al. 1980; Newell and Jordan 1983; Cranford and Gordon 1992; Iglesias et al. 1992; MacDonald and Ward 1994; Shumway et al. 1997; Bacon et al. 1998).

Scallops, however, typically do not produce copious amounts of pseudofeces, as compared to mussels and oysters. Bay scallops, *Argopecten irradians*, rejected only up to 25–35% of the algal cells filtered when exposed to bloom concentrations (0.55 to 1.46×10^6 cells mL^{-1} = 2.4 to 6.4 mg dry weight) of the pelagophyte *Aureococcus anophagefferens* (= *anophagefferens*) (Kuenstner 1988). MacDonald and Thompson (1986) reported that *Placopecten magellanicus* produced no pseudofeces when fed natural seston levels of 5 to 10 mg dry weight L^{-1} . In contrast, *Mytilus edulis* initiates pseudofeces production at seston concentrations between 2.6 and 5.0 mg L^{-1} depending on body size (Widdows et al. 1979). It has often been thought that bivalves only produce pseudofeces when exposed to concentrations of particles above a certain threshold value. However, studies by Ward et al. (1993) using endoscopic techniques have shown that pseudofeces are produced intermittently during the feeding process in many bivalves regardless of the concentration. It is likely that some pseudofeces are being produced even at low concentrations, although not in sufficient concentrations to be readily noticed or quantified unless specialised techniques are used.

The efficiency of particle selection in marine bivalves has been shown to be quite variable both within and among species, and is most likely related to palp size, seston conditions, or which indicator of seston quality is used to measure efficiency (Kjørboe and Møhlenberg 1981; Iglesias et al. 1992; Urrutia et al. 1996). Pectinids, like other marine bivalves have been shown to have the capability of rejecting poorer quality particles and improving the quality of the ingested ration. Recent studies on *Placopecten magellanicus* have confirmed the capability of this scallop species to reject particles of poorer quality preferentially based on both the organic composition of particles and the concentration of chlorophyll-*a* containing particles in the natural seston (Cranford and Gordon 1992; MacDonald and Ward 1994; Bacon et al. 1998). Results for *P. magellanicus* were consistent with those reported for other bivalve species such as *Mytilus edulis* and *Cardium edule* respectively, where the efficiency of selection diminished as the quality of the seston mixture declines (Bayne et al. 1993; Navarro et al. 1994) (Fig. 7.5). Both of the studies on *P. magellanicus* by MacDonald and Ward (1994) and Bacon et al. (1998) reported that the overall quantitative selection process, measured by the compensation index, was not effective at the lowest quality diets tested. Compensation index (CI) not only takes into consideration the quality of seston and pseudofeces, like most other indicators of sorting efficiency, but is unique because it takes into consideration quantities of material cleared and rejected. It is calculated as $\text{CI} = (I_Q / \text{SES}_Q) - 1$, where I_Q is the quantity of chlorophyll-*a* ingested and SES_Q is a measure of the quality of the seston, e.g., chlorophyll-*a* concentration. CI is the same as the index calculated by Navarro et al. (1992) and the benefit ratio (BR) given by Iglesias et al. (1992). In fact, for very poor-

Figure 7.5. Comparison of the quality of material in the seston (SES_Q, white box), with that in pseudofeces (PS_Q, black box) and that ingested (I_Q, striped box) by *Placopecten magellanicus* during each of the experimental periods. Data are from MacDonald and Ward (1994) and presented as mean $\pm$ SD, see their text for details.

quality diets, there may have been some evidence of organic enrichment of the pseudofeces rather than the ingested ration, or negative selection. Recognising that particle selection through the production of pseudofeces is a process of rejection MacDonald and Ward (1994) proposed the following explanation for negative selection. When poor-quality particles dominate the seston scallops may improve the quality of the material ingested by attempting to reject a high proportion of these particles. However, it may not be possible to retain the few relatively high-quality particles while rejecting the majority of low quality ones. This high rate of rejection may overwhelm the capacity of the system and result in non-selection or possibly even negative selection.

Both studies on particle selection in *Placopecten magellanicus* reported a negative relationship between compensation indices and clearance rates. This suggests that particle sorting on the labial palps is one of the limiting steps in the feeding process. In order for *Placopecten magellanicus* to increase the quality of the material ingested above 20% by particle selection through pseudofeces production they must reduce the volume of material entering the palps by reducing the clearance rate (MacDonald and Ward 1994). The strategy adopted by *P. magellanicus* when exposed to seston that varies in concentration and quality is to have relatively high clearance rates at low particle concentrations and as concentration increases significantly reduce clearance rate and increase the amount of pseudofeces produced. They rely on their pre-ingestive selection capabilities to reject poorer quality particles and enhance the quality of material ingested and maintain ingestion at higher concentrations.

It is well established that bivalves, including scallops, can selectively reject inorganic, sediment particles from mixed algal-sediment suspensions (see section on "Effects of

suspended sediments on feeding and growth". Kjørboe and Møhlenberg (1981) determined the efficiency of particle selection of ten species of suspension-feeding bivalves fed algal-sediment mixtures from the ratio of chlorophyll-*a* to dry weight in the suspension and pseudofeces. The only pectinid tested, *Aequipecten opercularis*, showed an intermediate selection efficiency (= 5.4). A maximum efficiency of 15.8 was measured for *Spisula subtruncata*, and a minimum value of 2.9 for *Mytilus edulis* from a low turbidity environment. A low selection efficiency (SE = 2.7) was also determined for *Placopecten magellanicus* fed a mixture of algae and bentonite clay (Cranford and Gordon 1992). Values obtained in the two studies are not strictly comparable, however, as Cranford and Gordon (1992) based their SE estimates on data obtained from retained rather than suspended particles. Low capacity for particle selection between inorganic and organic particles was confirmed when sea scallops were fed natural resuspended sediment containing benthic diatoms (Cranford and Grant 1990).

Bivalves are also capable of discriminating among algal cells of similar size in their diet. Using flow cytometry, Shumway et al. (1985) showed that the diatom *Phaeodactylum tricorutum* was selectively rejected in pseudofeces of *Placopecten magellanicus* when this alga was fed in combination with the dinoflagellate *Prorocentrum* sp. and the cryptomonad *Chroomonas salina*. Similarly, *Thalassiosira pseudonana* was preferentially rejected in pseudofeces when present in a mixed suspension with *C. salina*, *Prorocentrum* and the toxic dinoflagellate *Protogonyaulax tamarensis* (clone GT429) (Shumway and Cucci 1987). Differential clearance of various algal clones in a mixed suspension was also demonstrated using flow cytometry in three species of 1–2 mm juvenile scallops (Shumway et al. 1997). Selective removal from suspension was greatest in *Patinopecten yessoensis*, which showed significantly higher clearance rates for *Chroomonas salina* (clone 3C, ~6.1 μm), *Phaeodactylum tricorutum* (PHAE0, ~5.0 μm) and especially *Amphidinium carterae* (AMPHI, ~10 μm), than for *Isochrysis galbana* (T-ISO, 3–6 μm) or *Chaetoceros muelleri* (CHGRA, 4–9 μm). Lowest clearance rates were observed in all three scallop species with the smallest alga tested, a 2–3 μm unidentified prasinophyte (Omega 48). However, in *P. yessoensis*, algal size alone was not sufficient to explain the differences in clearance rate observed.

Selection in the gut or digestive gland-stomach complex is less well known, but it is believed that some bivalves can differentiate between particles within the gut and preferentially digest those particles that give the most nutritional benefit (Bricelj et al. 1984; Shumway et al. 1985; Lopez and Levinton 1987; Bayne et al. 1993; Wang and Fisher 1996). Postingestive selection may occur either by the retention of some particles longer than others in the stomach so that extracellular digestion has more time to act, or by directing some particles to the digestive gland for intracellular digestion. Cranford et al. (1998) found that two sizes of microspheres were passed at different rates through the gut of the sea scallop *Placopecten magellanicus*. While postingestive sorting in bivalves has been confirmed for several species, few studies have attempted to isolate the factors influencing selection among different particles presented simultaneously. *P. magellanicus* has been shown to be capable of distinguishing between particles of different size and density by retaining larger particles longer than smaller ones and lighter particles longer than denser ones (Brilliant and MacDonald 2000). These authors further showed that

P. magellanicus has well-developed postingestive sorting capabilities and could sort organic from inorganic particles and some particles based solely on chemical properties (Brillant and MacDonald 2002). These scallops retained protein-coated beads in the gut longer than uncoated beads of identical diameter and density.

7.2.8 Absorption Efficiency

Few studies have attempted to determine the utilisation efficiency with which the ingested ration is absorbed of algal diets by pectinids. Available data suggest, however, that scallops do not differ markedly from other bivalves in their absorption capabilities. Using ^{14}C labelling techniques Peirson (1983) found that adult *Argopecten irradians concentricus* absorbed most algal species tested with absorption efficiencies (AE) ranging between 78.1 and 89.9%. These values represent maximum efficiencies since they were determined at relatively low mean algal rations ($= 2 \text{ mm}^3 \text{ L}^{-1} = 468 \mu\text{g C L}^{-1}$). Only the chlorophyte, *Chlorella autotrophica*, was inefficiently absorbed (AE = 17.4%), as previously observed both in adult and larval oysters (Floyd 1953; Babinchak and Ukeles 1979). Low absorption efficiencies are generally attributed to the indigestible cell wall of this alga. The diatom, *Thalassiosira pseudonana* used in Peirson's study yielded the highest absorption efficiencies (89.9%). This is almost identical to a mean value of 89.7% obtained for bay scallops fed *T. weissflogii* by Kuenstner (1988) with the twin ^{14}C - ^{51}Cr radiotracer method. Veliger larvae of *Pecten maximus* inefficiently ingested and digested *Dunaliella primolecta*, and were unable to digest *Platymonas (Tetraselmis) suecica* (Le Pennec and Rangel-Dávalos 1985).

High absorption efficiencies are not sufficient to support growth of bivalves, and thus cannot be used as single predictors of food value. For example, Peirson (1983) reported a high absorption efficiency (83.3%) for *Dunaliella tertiolecta*, an alga known to support poor growth of oysters due to its deficiency in essential polyunsaturated fatty acids (Langdon and Waldock 1981). A high efficiency (90.6%) was also measured for *Aureococcus anophagefferens* (Kuenstner 1988); a species which caused starvation of bay scallops at bloom concentrations under field conditions (Bricelj et al. 1987a). Grant and Cranford (1989) reported that aged kelp (*Laminaria*) detritus was absorbed with high efficiency (70–80%) but did not support growth of adult *Placopecten magellanicus*.

A commonly used technique to estimate absorption efficiency is the Conover (1966) method which is based on the assumption that the organic and inorganic components must be ingested in the same proportions that occurs in the food supply (no ingestion selectivity). Adjustments must be made to the estimate of absorption efficiency if the bivalve is rejecting poorer quality particles through the production of pseudofeces otherwise the assumptions of the Conover ratio are violated. While some studies have shown that absorption efficiency increased with particle concentration, several recent studies on *Placopecten magellanicus* have shown absorption efficiency to be much better correlated to the quality than the concentration of the seston (Cranford 1995; Grant et al. 1997; Cranford et al. 1998; MacDonald et al. 1998). In many of these studies scallops were exposed to natural concentration of seston in the field or mixtures of microalgae and inorganic particles in the laboratory to mimic seston rather than various concentrations of

pure cultured microalgae alone. Absorption efficiency in field and laboratory studies consistently increased with the quality of the seston whether percent organics or the concentrations of nitrogen or carbon were used as indicators of quality (Fig. 7.6). Similar relationships between absorption efficiency and diet quality have been reported for *Chlamys islandica*, *Placopecten magellanicus*, *Mytilus edulis*, *M. galloprovincialis*, *Cerastoderma edule*, *Crassostrea gigas* and *Mya arenaria* (Vahl 1980; Bayne et al. 1987; Cranford and Grant 1990; Iglesias et al. 1992; Navarro et al. 1992; Navarro and Iglesias 1993; Hawkins et al. 1998; MacDonald et al. 1998).

Absorption efficiencies in *Argopecten purpuratus* did not significantly increase when the quality of the microalgae was improved by the addition of a lipid emulsion and were observed to decrease from 85 to 27% when carbohydrates were added to the microalgal diet (Navarro et al. 2000). However, clearance rates were stimulated by the diets supplemented with lipids resulting in a significant increase in absorption rates and a several-fold increase in scope for growth. In postlarvae of *A. purpuratus* absorption efficiency (AE) was found to correlate positively with the protein content of a mixed algal diet (*Isochrysis galbana*, T-ISO, and *Chaetoceros neogracile*) which ranged between 48 and 27% of total organics depending on culture conditions (Uriarte and Farías 1995; 1999). Absorption efficiency (AE) was highest (74.6%) when scallop postlarvae were fed the high-protein diet, and dropped to only 30.8% on the low-protein diet of the same algal species. High-protein diets were found to yield higher growth rates and survival of 1.8 mm postlarvae (also associated with high metabolic rates) but not in 6 mm juveniles suggesting that protein requirements may be greater during early scallop ontogeny (Uriarte and Farías 1999). It was also suggested that this transition in substrate utilisation might be associated with the change from a sedentary, byssally attached habit in *A. purpuratus* <5 mm, to a free-swimming mode above this size threshold. With the possible exception of *A. purpuratus*, absorption efficiency in pectinids is very similar to that observed in many other bivalves. There was no significant difference in absorption efficiencies between *P. magellanicus* and *Mya arenaria* when they were exposed simultaneously to a range of particle concentrations and qualities (MacDonald et al. 1998).

A strong and consistent relationship between a physiological response, such as absorption efficiency, and some characteristic of the food supply, such as organic composition can be used to improve the predictive power of numerical models of feeding behaviour and estimate carrying capacity of different environments. Cranford (1995) found that between 74 and 84% of the variance in absorption efficiency could be explained by the variance in food quality, expressed as the percentage of organic matter, C or N. Complete digestive acclimation to dietary conditions in *P. magellanicus* takes several days but its food supply fluctuates considerably over much shorter time scales (Cranford 1995). Rather than adjusting digestive processes in response to frequent dietary fluctuations this species acclimated to the lower quality diet and maintained a high state of digestive acclimation for at least 12 h to enhance absorptive capabilities and energy gain (Cranford 1995). In a seasonal field study of *P. magellanicus* and *Mytilus edulis* Cranford and Hill (1999) did not find good relationships between absorption efficiency and seston organic composition and a suite of environmental conditions were only able to explain

Figure 7.6. *Placopecten magellanicus*. Absorption efficiencies (mean $\pm$ SD) for scallops exposed to (A) natural seston in the field (from Cranford 1995) and (B) mixtures of microalgae and inorganic particles in the laboratory (from MacDonald et al. 1998).

28% of the variation in sea scallop and mussel ingestion rates. This work emphasises the complications associated with predicting feeding and digestion processes in bivalves and the need to have a better understanding of their previous history and other physiological processes such as metabolic demands associated with reproduction, for example (Kreeger 1993; Cranford and Hill 1999).

Absorption efficiency was not significantly influenced by salinity changes ranging from 30 to 18 ppt in *Argopecten purpuratus* (Navarro and González 1998). However, due to the strong inhibitory effect of low salinities on clearance and ingestion rates, absorption rate was highly reduced (by 96%) between 30 and 18 ppt.

7.2.9 Effects of Suspended Sediments on Feeding and Growth

Bivalve species differ considerably in their ability to cope with suspended sediment loads (see discussion by Bricelj and Malouf 1984), which may reduce growth rates by “diluting” the available food. Growth enhancement by low additions ($<5\text{--}10\text{ mg L}^{-1}$) of bottom sediments to algal diets were reported for *Mytilus edulis* (Kjørboe et al. 1981) and surf clams, *Spisula subtruncata* (Møhlenberg and Kjørboe 1981), but not for hard clams, *Mercenaria mercenaria* (Bricelj et al. 1984). Bricelj and Malouf (1984) hypothesised that bivalves which regulate ingestion primarily by a reduction in clearance rates (such as hard clams, softshell clams and scallops), are more likely to be vulnerable to high suspended sediment concentrations than bivalves such as mussels, oysters and surf clams which control ingestion mainly by increasing pseudofeces production (provided they are also capable of high ingestion selectivity). Although this simplified classification remains valid, recent work shows that intermediate strategies may also occur, and that the response to suspended sediment concentrations may also vary within a species depending on prevailing seston characteristics (Navarro and Iglesias 1993). A combination of both strategies occurs in *P. magellanicus* in response to mixtures of algae and inorganic, silicate particles (Bacon et al. 1998). Clearance rates declined sharply, and pseudofeces production increased with increasing seston concentration regardless of diet quality (% particulate organic matter, POM). However, sea scallops only rejected in pseudofeces 7 to 14% of the filtered ration, whereas rejection attained 40 to 93% in mussels, *Mytilus edulis* (Bayne 1993; Hawkins et al. 1996) and up to 58% in cockles, *Cerastoderma edule* (Navarro et al. 1994).

Shell growth rates of *Chlamys opercularis* were significantly depressed by moderate concentrations ($11\text{ to }37\text{ mg dry weight L}^{-1}$) of iron ore particles (Richardson et al. 1984). Iron ore suspensions exceeding ca. 25 mg L^{-1} caused abnormal thickening on the interior surface of shell valves presumably due to failure of the mantle edge to extend fully in the presence of high densities of inorganic particles. Tissue and shell growth rates of juvenile bay scallops, *Argopecten irradians*, were unaffected, however, by natural sediment concentrations between $5\text{ and }44\text{ mg L}^{-1}$ fed in combination with an algal diet (50×10^6 *Pseudoisochrysis paradoxa* cells L^{-1}) (Korol 1985). Duggan (1973) and Monical (1980) attributed reduced survival and growth of scallops (*Argopecten irradians* and *Hinnites multirugosus*) suspended near the bottom, relative to those at mid-depth, to increased suspended sediment concentrations. Depth-related differences in growth rates of *Argopecten irradians* were investigated by Korol (1985) in central Long Island Sound, N.Y., U.S.A. with contrasting results. Growth rates of bay scallops suspended within the turbidity zone, (1 m above a muddy bottom) were greater than at mid-depth and near the surface during the autumn. Growth enhancement near the bottom was attributed to 3–4 fold higher seston levels at depth relative to surface waters. In this study, chlorophyll and organic content of seston were relatively uniform throughout the water column in the fall, and near-bottom seston levels remained low, below 17 mg L^{-1} . Increased growth near the bottom presumably resulted from the combined effects of resuspension of bottom detrital material and increased availability of surface food particles due to breakdown of stratification at this time of the year. High-frequency characterisation of site-specific

seston quality and quantity and other environmental variables is thus critical in interpreting the effects of resuspended bottom material. A fall-winter study in a nearshore environment in Nova Scotia, Canada which included extensive environmental measurements showed an inconsistent relationship between soft-tissue growth of *P. magellanicus* deployed in cages and distance from the bottom (0 to 200 cm) over time (Emerson et al. 1994). However, by the end of the study period, soft tissue weight was significantly less on the bottom than at ≥ 50 cm above bottom suggesting that high seston loads near-bottom inhibited growth. Temperature and the ratio of particulate to organic to inorganic matter, POM/PIM, were found to be the best predictors of growth.

A diet consisting only of intertidal resuspended sediments was unable to support growth of *Placopecten magellanicus* (Cranford and Grant 1990). Scallops showed lower clearance rates for the suspended sediment diet than for an algal diet offered at a comparable ration, and low absorption efficiency (29% for organic carbon). Although a higher absorption efficiency was measured for sedimentary organic nitrogen (50%), the nitrogen content of sediment was extremely low. Thus negative values of scope for growth were obtained when calculated in terms of both carbon and nitrogen (Grant and Cranford 1991).

Studies on the effects of montmorillonite clays, e.g., bentonite (~ 2 μm median particle diameter) and attapulgite, the main components of water-based muds used in oil and gas drilling activities, on adult *Placopecten magellanicus*, have contributed to our understanding of the effects of fine-grained sediments in this important commercial species (see also chapter by Cranford in this volume). These clays are biologically inert and thus can be used to mimic fine-grained suspended sediment. Significant reduction in somatic and reproductive tissue growth of sea scallops, and extensive mortalities ($\sim 15\%$ and 45% after 15 and 30 days of exposure, respectively) were documented at only 10 mg bentonite clay L^{-1} in the presence of ambient food levels relative to controls with no clay addition (Cranford and Gordon 1992). Therefore *P. magellanicus*, which typically inhabits low turbidity environments with seston concentrations $< 2\text{--}5$ mg DW L^{-1} (e.g., Emerson et al. 1994; Grant et al. 1997), is highly intolerant of sediment loading. Higher, transient levels occur due to storm events and tidal and wind-driven bottom resuspension and anthropogenic activities (oil drilling, dredging).

In the presence of an algal diet, clearance rate (CR) of *P. magellanicus* declined exponentially with increasing clay concentration, resulting in 50% reduction at ~ 6 mg L^{-1} , whereas CR remained constant over the same range of dry weight concentrations of a pure algal diet (Fig. 7.7A, B). Low clay concentrations, < 1 mg L^{-1} , enhanced clearance rates relative to controls as observed in mussels and oysters. Increasing bentonite concentrations resulted in an exponential decline in ingestion rate of organic matter thus demonstrating a food dilution effect (Fig. 7.7C), and caused a decline in absorption efficiency when added to natural seston (Fig. 7.8A). Physiological responses returned immediately to control levels upon removal of bentonite from the suspension. Integration of physiological data allowed calculation of a negative scope for growth at bentonite concentrations ≥ 8 mg L^{-1} (Fig. 7.8B). Negative effects on growth of bentonite can thus be attributed to the combined effects of reduced ingestion rate of organic matter and reduced absorption efficiency, which lead to reduced absorption rate. Reduced metabolic rate,

Figure 7.7. *Placopecten magellanicus* adults. Effects on clearance rates (mean $\pm$ SD) of increasing concentration of algae (*Tetraselmis suecica*) (A), compared to those of PIM (bentonite clay) added to a 1 mg L⁻¹ algal suspension (B); effects of clay on calculated algal ingestion rate (algal ash-free dry weight, AFDW, per hour) (C). Source: modified from Cranford and Gordon (1992).

documented at concentrations ≥ 4 mg L⁻¹ (Cranford et al. 1999) is insufficient to compensate for food dilution effects in this species.

Compensation of food dilution by inorganic particles may also occur via selective rejection of PIM in pseudofeces and can be quantified by the compensation index (CI), as selection efficiency alone does not take into account the amount of pseudofeces produced (see section 7.2.7 on particle selection). In *P. magellanicus* exposed to mixtures of algae and silicate, a positive CI, indicative of the capacity to enhance the quality of ingested vs. available particles, was obtained at seston concentrations 3–7 mg L⁻¹ and when diet quality (% POM) was $\geq 50\%$ (Bacon et al. 1998). This compensation strategy was ineffective (negative CI values) when seston quality was very low (25% POM).

Figure 7.8. *Placopecten magellanicus* adults. Effects of increasing concentrations of PIM (bentonite clay) added to natural seston on A) ingestion rate and percent absorption efficiency (AE) of particulate organic matter (POM). B) Effects of bentonite and water-drilling muds (composed primarily of bentonite with some barite) on scope for growth (plotted from data in Cranford et al. 1999, for unconditioned scallops, with no prior exposure to clay).

It is now well recognised that functional responses of bivalves may vary considerably with the type of suspended particulate matter, i.e., artificial diets (e.g., algae and inert particles) vs. natural suspensions of low organic content (Bayne et al. 1993; Hawkins et al. 1996). In *P. magellanicus* the reduction in CR and in ingestion rate of organic matter caused by bentonite additions was greater when scallops were fed natural seston than a unialgal diet (Cranford and Gordon 1992). Increasing concentrations of natural, resuspended bottom sediment from Georges Bank (that passed through a 102 μm mesh

sieve) resulted in an exponential decline in clearance rates, but in contrast to bentonite, this decline was only detected at concentrations $\geq 12 \text{ mg L}^{-1}$ (Grant et al. 1997). The threshold concentration for visible pseudofeces production was also higher for resuspended sediment, ($>10 \text{ mg L}^{-1}$) than that found for bentonite ($\sim 2 \text{ mg clay L}^{-1}$) by Cranford and Gordon (1992). Thus resuspended bottom sediment ($\geq 5 \mu\text{m}$ median size) was less deleterious to adult *P. magellanicus* than bentonite and can even contribute a potential food source under conditions of food limitation. Grant et al. (1997) estimated that sea scallops could absorb organic matter ($\sim 30\%$ of dry weight) associated with resuspended bottom sediment with $\sim 40\%$ efficiency. Inorganic clay particles may also provide a potential food source via adsorption of dissolved organic matter. In this study sea scallop gill retention efficiency of resuspended sediments attained 100% at $\sim 5 \mu\text{m}$ and did not decline with increasing sediment load (Grant et al. 1997), as was observed with clay (Cranford and Gordon 1992).

Effects on scallop feeding physiology can also vary with the degree of aggregation of individual sediment particles. Fine, clay-sized particles readily form larger flocs or aggregates in seawater, and it remains unclear whether they are again broken down to individual particles during bivalve feeding. Scallops are known to ingest relatively large individual particles up to $350 \mu\text{m}$ for *P. magellanicus* (Shumway et al. 1987) and $950 \mu\text{m}$ for *Patinopecten yessoensis* (Mikulich and Tsikhon-Lukamina 1981) and could thus potentially ingest large flocs even if these were not disaggregated on the gills. White (1997) found that flocculation increased the ability of adult *P. magellanicus* to retain small ($<7 \mu\text{m}$) clay particles and thereby increased the availability of clay for ingestion. For the preparation of feeding suspensions in this study rapid formation of large flocs was induced by the addition of gelatin, which may lead to formation of more robust flocs than those occurring in natural seston. Lyons and Ward (2003) also found that flocs (marine aggregates) increased the uptake of small ($1 \mu\text{m}$) fluorescent beads in *P. magellanicus*.

High concentrations of PIM not only result in food dilution but may also cause direct and irreversible physical damage to the bivalve gill thus impairing feeding capacity. The filibranch gill of scallops is more vulnerable to this type of sublethal structural damage than the eulamellibranch gill. In adult *Placopecten magellanicus* heavy damage resulting from the breakdown of the ciliary junctions (cilifers) between gill filaments occurred after 4 to 9 days of exposure to attapulgitic clay at concentrations of 0.5 to 1 mg L^{-1} and moderate damage was observed at 0.1 mg L^{-1} (Morse 1982).

The contribution of PIM to total seston has been used as an index of the nutritional quality of available particles. Vahl (1980) found that absorption efficiencies of *Chlamys islandica* (ranging between 10 and 55%) were inversely related to the fraction of inorganic matter in the seston, and that the ratio of PIM/POM (particulate inorganic matter to organic matter) provided a good correlate of growth in this population. Enhanced growth rates of *C. islandica* held in suspended culture near the sea surface, compared to those held at 40 m, were also attributed to depth-related differences in PIM/POM (Wallace and Reinsnes 1985). These authors recommended use of the PIM/POM ratio as an index of the nutritional value of seston. Adverse effects on growth of scallops were predicted when the PIM/POM ratio exceeded a critical value of 3.5 (i.e., when inorganic material comprises more than 78% of the total seston). This supports Vahl's (1980)

estimate, obtained by extrapolation, that no POM would be absorbed when PIM comprises more than 80% of the seston (PIM/POM = 4). Similarly, using controlled mixtures consisting of a fixed concentration (1 mg L^{-1}) of algae or natural seston and varying concentrations of PIM (bentonite clay) to manipulate diet quality, Cranford (1995) found an inverse logarithmic relationship between absorption efficiency (AE) of organic matter of the sea scallop, *P. magellanicus*, and increasing bentonite levels. The relationship between AE and diet quality (Q) whether expressed as the % of POM, particulate organic carbon, POC, or nitrogen, PON, per unit dry weight seston) was described (after Bayne et al. 1987) by the following exponential equation:

$$\text{AE} = a [1 - e^{-b(Q-c)}] \quad (2)$$

Where, a = the maximum value of AE, >92%, b = the rate of increase of AE with increasing diet quality, and c = diet quality at which AE = 0. This coefficient was estimated at 14% POM/DW (PIM/POM = 6) for *P. magellanicus* in this study, compared to 7% in *Mytilus edulis* (reviewed by Cranford 1995) and has been suggested as an index of a bivalve's capacity to survive in a nutritionally poor environment (Navarro and Iglesias 1993). Adverse effects on sea scallop growth were found at a relatively low PIM/POM ratio of 1.5 (addition of 10 mg L^{-1} bentonite) (Cranford and Gordon 1992, Cranford 1995), below the critical threshold proposed above for *C. islandica*. Interspecific comparisons from different studies must be interpreted with caution, however, as the coefficients in the equation can vary considerably within a species as a function of environmental conditions, and were shown to vary between laboratory and field studies (Cranford et al. 1998).

Scallops appear to be particularly susceptible to siltation both in the laboratory (Castagna 1975) and in the field (Duggan 1973; Tettelbach et al. 1985). In bay scallops, *A. irradians*, burial by shifting sediments has been suggested as a significant cause of mortalities during the winter when low temperatures result in reduced activity (Tettelbach et al. 1990). Laboratory studies confirmed that juveniles (19–25 mm in shell height) partially (2/3) covered by a 1 cm-deep sediment layer at temperatures $<10^{\circ}\text{C}$ showed significant mortalities relative to unburied controls by the end of 10 weeks. Therefore, byssal attachment to elevated substrates in juveniles and some adult scallops may provide a mechanism of avoiding burial by fine-grained sediments and exposure to high near-bottom turbidities, in addition to a predator refuge. Using ciliary activity of gill sections as a physiological index Yamamoto (1960) found that the tolerance of juvenile *Patinopecten yessoensis* to suspended silt and low oxygen tension increased with scallop size (over the range 17 to 100 mm). Since high turbidity and low oxygen levels are both conditions associated with uncompacted, fine-grained sediments, Yamamoto's findings explain the often observed low survival of juvenile scallops in muddy bottoms. Growth rates of adult scallops can also be adversely affected in soft, muddy substrates; Gruffydd (1974) found that the maximum shell size of *Pecten maximus* from the North Irish Sea decreased significantly with increasing mud content of sediments.

7.2.10 Effects of Flow on Feeding and Growth

Studies of natural populations of shallow water pectinids such as *Argopecten irradians*, have generally found that larger size and faster growth rates are associated with areas of relatively strong currents (Belding 1910; Gutsell 1930; Marshall 1960). Emigration rates of the bay scallop *Argopecten irradians concentricus* increased with scallop density but only in the presence of a high tidally oscillating flow regime of 28 cm s^{-1} but not at flows of 10 cm s^{-1} (Powers and Peterson 2000). This study illustrates how flow can facilitate biological interactions and influence density dependence. Reduced growth rates of suspension-feeding bivalves in areas of low current speeds and/or high population densities are attributed to a reduction in seston supply in the benthic boundary layer (Fr  chette and Bourget 1985).

Excessively high current speeds could, however, potentially reduce growth by inhibiting the scallops' feeding activity. Kirby-Smith (1972) investigated the effect of current speed (within the range 0.2 to 12.8 cm s^{-1}) on growth of adult *Argopecten irradians concentricus* in an apparatus consisting of pipes with different outflow diameters. He found that shell growth rate and condition (muscle weight/shell height) decreased at current speeds exceeding about 6 cm s^{-1} . It has been noted however, that the current speeds reported in his study, estimated by dividing the observed volume discharge rate by the cross-sectional area of the pipe, underestimate the speeds actually experienced by the scallops (Eckman et al. 1989). Clearance rates in *Placopecten magellanicus* are a unimodal function of flow: they are positively related with flow speed below $5\text{--}10 \text{ cm s}^{-1}$, independent of flow at intermediate flows of 10 to 20 cm s^{-1} and decline when velocities exceed 15 to 20 cm s^{-1} (Wildish and Kristmanson 1985; Wildish et al. 1992; Wildish and Saulnier, 1993). Wildish et al. (1992) found that higher seston concentrations could offset the velocities at which feeding inhibition occurs.

Many studies on scallop feeding activity have been undertaken via short-term experiments in static chambers or in poorly defined flow fields. Feeding activity in suspension-feeders measured under laboratory conditions may differ from feeding rates observed in the dynamic boundary layer flows found in coastal waters (Rubenstein and Koehl 1977, LaBarbera 1981). In a unique flume study Pilditch and Grant (1999a) exposed the sea scallop *Placopecten magellanicus* to increasing and decreasing concentrations of food and incremental changes in flow speeds between 5 and 25 cm s^{-1} . These authors did not find a positive correlation between clearance and flow speeds but observed clearance to be independent of flow speed between $5\text{--}15 \text{ cm s}^{-1}$ and inhibited at 25 cm s^{-1} . However, clearance rates were different in the ascending and descending phases of the experiments with a lower flow speed of $10\text{--}15 \text{ cm s}^{-1}$ inhibiting feeding on the descending phase. They suggested that the response to flow speed may be a function of feeding history whereby clearance may be inhibited at lower flow velocities after feeding on high concentrations of phytoplankton. This research emphasises the direct effects of flow, its interaction with seston concentration and the significance of short-term feeding history in regulating scallop feeding rates.

Evidence of a growth limiting upper velocity obtained in experimental flume systems appears to contradict field observations. For example, Eckman et al. (1989) report that

juvenile *Argopecten irradians* within dense eelgrass beds (1,100 shoots m⁻²) in Back Sound, North Carolina, U.S.A. regularly experience current speeds as high as 5–28 cm s⁻¹. Adult giant scallops (*Placopecten magellanicus*) in the Bay of Fundy are found where depth-integrated maximum tidal velocities exceed 100 cm s⁻¹ (Wildish and Peer 1983) and are thus well above the critical thresholds determined experimentally. Similarly, Bricelj et al. (1987a) found highest reproductive output and muscle condition of adult *A. irradians* in a site where surface currents can exceed 70 cm s⁻¹. Flow velocities within the benthic boundary layer will be lower, however, than depth integrated or free stream velocities. Furthermore, scallops often occupy depressions in bottom sediments (recessing) (Caddy 1968) where they may avoid high flow velocities. Wildish and Kristmanson (1988) attempted to reconcile this apparent contradiction in a study that examined the influence of periodic changes in flow regime on growth of *Placopecten magellanicus*. Scallops were found to maintain maximal rates of shell growth as long as they were exposed to growth limiting current velocities (>10 cm s⁻¹) less than a third of the time. In contrast to studies evaluating the effect of scallop orientation on growth in flumes using steady current velocities, Claereboudt et al. (1994) did not observe any differences in growth of *P. magellanicus* related to orientation relative to current direction in the field. However, these authors did find a reduction in tissue growth at their high velocity site (16 cm s⁻¹) consistent with other studies of sea scallops in flumes where growth was reduced at velocities exceeding 10 cm s⁻¹ (Wildish et al. 1987; 1992). Pearl nets decreased water flow by 46–61% thereby reducing velocities that inhibit feeding and result in greater growth inside the nets than outside for scallops held at the high velocity site. This is in contrast to observations at the low velocity site (9 cm s⁻¹) where the pearl nets reduced flow inside to the point where growth inside the nets was significantly lower possibly due to seston depletion (Claereboudt et al. 1994).

In contrast with the results reported earlier, Cahalan et al. (1989) found that growth rates of juvenile (3–7 mm) bay scallops, *Argopecten irradians*, determined in a flume, were independent of current speed between 1 and 15 cm s⁻¹. Eckman et al. (1989) found that shell growth of juvenile *A. irradians* (8–14 mm) declined gradually with increasing flow velocity over the range 1.4 to 17.2 cm s⁻¹, irrespective of the scallops' orientation to the flow. At any given flow velocity, scallops grew more rapidly when oriented with anterior margins facing upstream, their preferential orientation. There was no evidence however, of a sharp decline in growth above some threshold flow velocity. Furthermore, a statistically significant effect of flow velocity on growth was only detected for scallops with their anterior opening oriented downstream. In this study responses of scallops to current speed and turbulence were determined in a series of pipes with outflows of different diameters, and low velocities were measured directly with a thermistor-bead flowmeter.

Juvenile bay scallops in their natural habitat live byssally attached to elevated substrates, and therefore routinely experience flows greater than 3 cm s⁻¹, and as high as ca. 17 cm s⁻¹ (Eckman et al. 1989). Given their preferential orientation, they are unlikely to remain in an unfavourable orientation where growth is more strongly inhibited by increasing flow velocity. Eckman et al. (1989) additionally found that growth rates were independent of the presence or intensity of turbulence. Animals were tested in flows

ranging from laminar to fully turbulent (Reynolds number = 840 to 5,600), with flow velocity held within a narrow range of 1.7 to 3.9 cm s⁻¹.

In a laboratory study that examined the effects of flow speed and orientation on growth of juvenile *Nodipecten subnodosus*, highest shell and tissue growth rates were obtained at flow speeds between 5 and 10 cm s⁻¹ and when scallops were in their natural orientation (ventral, inhalant margin oriented towards the flow) (García-Esquivel et al. 2000). This study was conducted in tubes cut in half, in which flow was controlled via a recirculating pump, and current velocities were determined using rhodamine dye. Free scallops showed reduced tissue weight at the highest speed tested (15 cm s⁻¹) even though this scallop species is known to experience current velocities over 100 cm s⁻¹ in its natural habitat in Baja California, Mexico. This high current speed caused detachment of juveniles as well as growth inhibition. Flow had no significant effect on growth when scallops were oriented horizontally against the flow, an orientation, which resulted in the slowest growth.

7.2.11 Effects of Harmful and Toxic Algae

Like other suspension-feeding bivalve molluscs, scallops accumulate toxins associated with harmful algal species. In most instances (but not all!), adductor muscles do not accumulate toxins and are thus safe for human consumption even in the presence of harmful algae. Whole scallops are a serious threat to public health, especially since many species bind the toxins in various tissues for extended periods of time and are rendered unsuitable for human consumption even when blooms are not evident (see Shumway and Cembella 1993; Bricelj and Shumway 1998 and references therein). In addition to becoming vectors for these algal toxins, many species of scallops are themselves adversely affected by the toxins (Table 7.3).

Perhaps the best understood responses of scallops to harmful algae are those associated with brown tides caused by the picoplanktonic alga *Aureococcus anophagefferens* in mid-Atlantic, U.S.A. estuaries. In eastern Long Island, NY, where blooms have recurred since 1985, brown tides have led to recruitment failure, growth inhibition and decimation of local bay scallop (*Argopecten irradians*) populations (reviewed by Bricelj and Lonsdale 1997) despite intensive reseeded efforts (Tettelbach and Wenczel 1993). The mid-summer, main spawning period of scallops has been shown to overlap with the period of occurrence of *A. anophagefferens* (Bricelj et al. 1987a). Due to their small size (~2 µm) *A. anophagefferens* cells are retained with only 36% efficiency by adult bay scallops (Cosper et al. 1987). However, their negative effects are attributed to an unknown, dopamine-mimetic, bioactive/toxic metabolite associated with brown tide cells, which suppresses the activity of gill lateral cilia (Gainey and Shumway 1991) and thus clearance rates of bivalves such as *Mytilus edulis* and *Mercenaria mercenaria* (Tracey 1988; Bricelj et al. 2001). These effects are observed even when non-toxic algae of high food value are present in a mixed phytoplankton assemblage with *A. anophagefferens*. Toxic effects require direct contact with brown tide cells and do not appear to be associated with the production of dissolved toxic exudates (Ward and Targett 1989). It is of interest to note that *in vitro* trials by Gainey and Shumway (1991) did not

document gill ciliary inhibition by brown tide in adult *A. irradians*, although natural populations of this species are known to be adversely affected by brown tides.

Although *A. anophagefferens* bloom densities in the field can attain $1\text{--}2 \times 10^6$ cells mL^{-1} , the inhibitory effect on bivalve feeding is concentration-dependent and in short-term studies of juvenile hard clams occurred above a threshold cell density of $\geq 35 \times 10^3$ cells mL^{-1} (Bricelj et al. 2001). Densities from 1.9×10^5 to 7.5×10^5 *A. anophagefferens* cells mL^{-1} were found to significantly reduce survival and growth of bay scallop larvae in laboratory studies, even in the presence of nutritious algae (Gallager et al. 1989). Scallop larvae were able to maintain ciliary-driven swimming activity, as well as capture of nutritious algae in the presence of *Aureococcus*. However, the latter caused increased rejection of non-toxic algae from the oesophagus and thus reduced ingestion rate. Thus, Gallager et al. (1989) suggested that the mechanism of action of brown tide cells in larvae made differ from that of adults, in that *Aureococcus* may interfere with the chemosensory function of larvae rather than ciliary activity.

The ichthyotoxic flagellate *Prymnesium* spp. (isolate 97-20-1) at 10^5 cells mL^{-1} was found to elicit toxic effects in juvenile bay scallops, *A. irradians*: copious mucus and pseudofeces production and valve gape not responsive to stimulation, necrosis of the digestive gland and gill as revealed by histopathology and presence of moribund or dead animals within 24 h of exposure (Wikfors et al. 2002).

Several species of dinoflagellates, the most common components of toxic algal blooms, have been shown to have negative impacts on scallops. Yan et al. (2001) reported inhibition of egg hatching success and larval survival of *C. farreri* when exposed to intact cells and cell fragments of *Alexandrium tamarense* (isolate from Daya Bay, PRC). Hatching rate of *C. farreri* decreased to 30% of controls after exposure to *A. tamarense* cells or cellular fragments at 100 cells mL^{-1} and was only 5% after exposure at 500 cells mL^{-1} . Larval (D-stage) survival rates decreased significantly after exposure for 6 d at 3000 cells mL^{-1} and above; no larvae survived after 14 d exposure at 10,000 cells mL^{-1} or 20 days at 5,000 cells mL^{-1} . However, these experimental concentrations exceed environmental levels by several orders of magnitude. Exposure to saxitoxin (STX) standard did not inhibit egg hatching, suggesting that an unknown metabolite, rather than PSP toxins, was the causative agent of hatching failure. These results may have far reaching implications for devastation of field or hatchery populations exposed to this common dinoflagellate.

While heart rate, feeding rate, and irrigation rates of *P. magellanicus* were unaffected by the presence of PSP-producing *A. tamarense* (at 10^4 cells L^{-1}) (Shumway and Cucci 1987; Gainey and Shumway 1988a, b), scallops did produce copious amounts of a white, mucus-like substance, and the animals exhibited a striking escape response with either violent swimming activity, partial, sustained shell-valve closure, or a combination of the two. It was suggested that this increased metabolic output might prove detrimental to the scallops if it continued for any extended length of time. This type of avoidance response was not described in other scallop species fed PSP-producing dinoflagellates, e.g., *Pecten maximus* fed *A. minutum* (Bougrier et al. 2001). Bivalve species that are resistant to the effects of PSP toxins can assimilate and grow on toxic *Alexandrium* spp.. Absorption efficiency of organic matter (OM) [(OM absorbed/OM filtered) $\times 100$] of *P. maximus* fed

Table 7.3

A summary of toxic and noxious algal species associated with scallops (after Shumway 1990; Shumway and Cembella 1993 and Landsberg 2002). Where known, strain is given below the algal species name followed by cell toxicity and concentration. Algal species are given as in the original publications with current taxonomic status added. See text for details.

Algal Species	Scallop Species	Effects	Location	Reference
Dinoflagellate Species				
<i>Alexandrium tamarense</i> (ATHK; 1.175×10^{-9} g STX eq cell ⁻¹ ; see text for cell concentrations)	<i>Chlamys farreri</i> (larvae and juveniles)	Inhibition of egg hatching success after 36 h exposure at 100 cells mL ⁻¹ ; decreased larval survival after 6 d at 3000 cells mL ⁻¹	Laboratory	Yan et al. 2001
<i>Protogonyaulax tamarensis</i> (= <i>A. tamarense</i>) (GT429; 5×10^5 cells L ⁻¹)	<i>Placopecten magellanicus</i> (adults)	Violent swimming and mucus production	Laboratory	Shumway and Cucci 1987; Gainey and Shumway 1988b
<i>Ptychodiscus brevis</i> (= <i>Karenia brevis</i>) ($5\text{--}500 \times 10^3$ cells L ⁻¹)	<i>Argopecten irradians</i>	Adult scallop mortality (21%); almost total recruitment failure	North Carolina (Field)	Summerson and Peterson 1990
<i>Karenia brevis</i> (<900 cells mL ⁻¹)	<i>Argopecten irradians</i> (larvae)	Delayed metamorphosis and larval development, decreased filtration and mortality	Laboratory	Leverone and Blake 2001
<i>Gymnodinium veneficum</i>	<i>Pecten maximus</i> (adults)	100% mortality within 1 h of exposure	Laboratory	Abbott and Ballantine 1957
<i>Gyrodinium aureolum</i> (PLY 497; 10^5 cells L ⁻¹)	<i>Argopecten irradians</i> <i>Placopecten magellanicus</i> (juveniles <15 mm)	Some evidence of poor food quality, no obvious toxic effects in either species at cellular level; 100% mortality in <i>A. irradians</i> ; no mortality but copious mucus production in <i>P. magellanicus</i>	Laboratory	Smolowitz and Shumway 1997; Lesser and Shumway 1993
<i>G. cf. aureolum</i> (up to 5×10^5 cells L ⁻¹)	<i>Pecten maximus</i>	High mortality in postlarvae and juveniles; cessation of feeding in larvae; inhibition of reproduction and growth	Bay of Brest, France and laboratory	Lassus and Berthome 1988; Erard- LeDenn et al. 1990
<i>Heterocapsa circularisquama</i> ($10^5\text{--}10^6$ cells L ⁻¹)	<i>Chlamys nobilis</i> (adults)	Mass mortalities	Ago Bay, Japan	Matsuyama et al. 1995; 1999; personal communication

<i>Lingulodinium polyedrum</i> (= <i>Gonyaulax polyhedra</i>) (as <i>Gonyaulax</i> sp.) (10^7 cells L ⁻¹)	<i>Leptopecten</i> [as <i>Pecten</i>] <i>L. latiauratus</i>	Mortalities (probably a result of anoxia and high temperature, not toxins)	Ensenada, Baja California, Mexico	Stohler 1959
<i>Prorocentrum lima</i>	<i>Argopecten irradians</i> (juveniles; pre-reproductive adults)	Reduced absorption efficiency relative to <i>Thalassiosira weissflogii</i>	Laboratory	Bauder et al. 2001
<i>Prorocentrum minimum</i>	<i>Argopecten irradians</i> (post-set; 0.61g mean live weight)	Mortality, atrophy and necrosis of the digestive gland absorptive cells, and systemic effects	Laboratory	Wikfors and Smolowitz 1993, 1995; personal communication
<i>Prymnesium</i> sp. (10^5 cells mL ⁻¹)	<i>Argopecten irradians</i> (juveniles, 10 and 50 mm)	Violent twitching, abundant mucus production; valve gape; all moribund or dead within 24h; severe, acute total or near-total necrosis of digestive gland and ducts, gill and other tissues; dead hemocytes	Laboratory	Wikfors et al. 2002
<i>Pfiesteria shumwayae</i> (100–2,500 cells mL ⁻¹)	<i>Argopecten irradians</i>	Rapid mortality caused by aggressive feeding on larvae by <i>Pfiesteria</i> ; no mortality when cells were isolated from scallops in dialysis tubing	Laboratory	Shumway and Springer 1996; unpublished
<i>Pfiesteria piscicida</i> (150–3,500 cells mL ⁻¹)	<i>Argopecten irradians</i>	Decrease or cessation of clearance rate in adults; mortality in larvae, spat and adults	Laboratory	Springer et al. 2000, 2002
Pelagophyte Species				
<i>Aureococcus anophagefferens</i>	<i>Argopecten irradians</i>	Larval shell growth reduced and increased mortalities	Laboratory	Gallager et al. 1989
<i>A. anophagefferens</i>	<i>Argopecten irradians</i>	Mass mortalities	Long Island, NY	Cosper et al. 1987
<i>A. anophagefferens</i>	<i>Argopecten irradians</i>	76% reduction in adductor weights; recruitment failure	Long Island, NY	Bricelj et al. 1987b
Diatom Species				
<i>Rhizosolenia chunii</i> ($56\text{--}187 \times 10^3$ cells mL ⁻¹)	<i>Pecten alba</i> (adult)	Digestive gland lesions and subsequent mortalities possibly caused by <i>R. chunii</i>	Port Phillip Bay, Australia	Parry et al. 1989
<i>Rhizosolenia delicatula</i> <i>Ceratulina pelagica</i> (7.3×10^5 cells L ⁻¹)	<i>Pecten maximus</i> (adult)	Decline in growth rate; clogged gills affecting feeding and respiration	Bay of Brest, France	Lorrain et al. 2000; Chauvaud et al. 1998

A. minutum was 42% (Bougrier et al. 2001) and absorption efficiency [(OM absorbed / OM ingested) x 100] of a highly toxic strain of *A. fundyense* by *Mytilus edulis* was 60–63% (Bricelj et al. 1990).

Very limited information is available on the effects of the brevetoxin-producer *Ptychodiscus brevis* (= *Karenia brevis*) on bivalve molluscs, although this species is known to cause mass fish mortalities. Bay scallops, *Argopecten irradians*, appear to be particularly sensitive to the toxic effects of this dinoflagellate. A mortality of 21% and almost total (98%) recruitment failure of *A. irradians* was reported by Summerson and Peterson (1990) for scallops exposed to a renegade bloom of this dinoflagellate in North Carolina. Clearance rates of juvenile bay scallops were significantly reduced at concentrations ≥ 50 intact cells *K. brevis* mL⁻¹ as well as in the presence of lysed cells (Leverone and Blake 2002). These authors also found that *K. brevis* inhibited metamorphosis and caused mortalities of bay scallop larvae above 500 cells mL⁻¹. While this dinoflagellate species is usually restricted to the Gulf of Mexico, this example is a clear indication of the devastating impacts that harmful algal blooms can have on scallop populations and a warning with regard to potential impacts at aquaculture sites.

In complementary studies (Lesser and Shumway 1993; Smolowitz and Shumway 1997), juvenile *Argopecten irradians* and *Placopecten magellanicus* were exposed to bloom conditions (10^5 cells L⁻¹) of *Gyrodinium aureolum* for a week. These studies clearly demonstrated a species-specific impact of this alga on the scallops. Mortality was 100% in *A. irradians* and zero in *P. magellanicus*. Reduced clearance rates were noted in *A. irradians* and production of copious amounts of mucus were noted in *P. magellanicus*. No mortalities were noted in either species when exposed to *Alexandrium tamarense*. At the cellular level, *G. aureolum* had a marked effect on the digestive gland of *A. irradians*. There was a significant decrease in the height of absorptive cells and increased lumen diameter which, at least, suggest poor food quality of *Gyrodinium*. There was no direct evidence of toxic effects such as necrosis and sloughing of digestive gland epithelial cells in the digestive gland. Some animals showed inflammation in the kidney but the cause was not delineated. No such impacts were noted in *P. magellanicus*. Erard-LeDenn et al. (1990) noted minor mortalities in 2-year old *P. maximus* exposed to *G. aureolum* and also noted a 'stress ring' on shells of exposed animals in the field, clearly indicating growth inhibition. Postlarvae (1 mm) experienced major die-offs (100% at one site, 85% at another) at cell concentrations of 2×10^5 cells L⁻¹. These blooms were extensive and lasted several weeks during the summer period and caused mass mortalities of the individuals in the nurseries and trays. Growth of juveniles (5–30 mm shell height) stopped completely for one month and resumed when the red tide vanished. In addition, the adult scallops exhibited abnormally low gonadal indices. Laboratory studies revealed a decreased filtration rate of *P. maximus* exposed to *G. aureolum* and also demonstrated differences between toxicity of different strains of *G. aureolum*.

Heterocapsa circularisquama, a toxic dinoflagellate from Japanese waters has been implicated in mass mortalities of several species of bivalve molluscs, including scallops (*Chlamys nobilis*; Matsuyama 1999; Matsuyama et al. 1996, 2001). While empirical data on scallop mortality are not available, this alga is known to be a molluscicide and it has had devastating impacts on aquaculture for various species including mussels, oysters and

pearl oysters in Japanese waters. Establishment of scallop culture in areas prone to this alga would be very risky business.

Impacts of the dinoflagellate, *Prorocentrum minimum*, on postlarval scallops, *A. irradians*, were studied by Wikfors and Smolowitz (1993) as part of an investigation of observed poor growth rates in caged hard clams, *Mercenaria mercenaria*. They provided scallops with mixed diets of T-ISO and *P. minimum* in varying ratios. Daily ration was equalised to 0.012 mL of packed cells per individual scallop. No algal diet supported good, consistent growth of scallops and survival varied between treatments, with 100% mortality noted in one week in one trial and four weeks in a second trial. Histological observations after one week of exposure to the mixed diet revealed poorly developed digestive diverticula and attenuation of the epithelium with abnormal vacuolation and necrosis. They also noted the presence of large thrombi in the open vascular system of the mantle, digestive diverticula, heart, gill, and kidney tissues, suggesting systemic effects of a toxin. Since *P. minimum* is a common component of the phytoplankton during the summer in scallop growing areas, there is considerable potential for detrimental impacts on both natural and cultured populations of *A. irradians*. Exposure of juvenile and adult *Argopecten irradians*, to *Prorocentrum lima*, a producer of diarrhetic shellfish poisoning (DSP) toxins which can act as potent phosphatase inhibitors, had no adverse effects on survival of scallops over a 2-wk period (Bauder et al. 2001). In this study there was no evidence of abnormal behaviour (shell clapping or avoidance by swimming) and byssal attachment and climbing of juveniles remained unaffected. Feeding (clearance rates) were comparable to those of controls offered an equal biovolume of non-toxic diatoms.

Scallops exposed to the dinoflagellate, *Pfiesteria* spp. are impacted by both toxins and physical attack by *Pfiesteria* (Springer et al. 2002; Shumway, unpublished). Bay scallop larvae (*A. irradians*) are aggressively fed upon by *Pfiesteria piscicida* zoospores (all functional types) within minutes of zoospore introduction. Left in direct contact with the zoospores, the larvae are dead within 30–45 minutes. High rates of larval mortality have also been observed in experiments where toxic zoospores were constrained within dialysis tubing. These results suggest the presence of dissolved toxin(s). *P. shumwayae* zoospores are even more aggressive in their feeding response towards *A. irradians* larvae (death within 10–15 minutes) although the same cultures cannot induce larval mortality when constrained within dialysis tubing.

Juvenile and adult bay scallops rapidly cleared *P. piscicida* from suspension at concentrations ranging from 150–3,500 cells mL⁻¹ (Springer et al. 2002; Shumway unpublished). Toxic zoospores were cleared from suspension at progressively slower rates than nontoxic (algal fed; TOX-B, NON-IND) zoospores. A significant difference in grazing rates also exists between juvenile scallops presented with freshly isolated *P. piscicida* (TOX-B) versus those fed non-inducible cultured isolates (3+ months in culture). This is presumably due to residual toxicity in the TOX-B cultures. *P. shumwayae* is cleared from solution at a relatively lower rate than observed for *P. piscicida* (concentrations ranging from 100–2,500 cells mL⁻¹) but the cause for these observed differences has yet to be determined. The presence of *Pfiesteria* spp. has already had devastating impacts on at least one bivalve hatchery in North Carolina.

Unlike dinoflagellates, diatoms have rarely been attributed harmful effects on shellfish in general or scallops specifically (see Shumway 1990; Shumway and Cucci 1987; Gainey and Shumway 1988b). Unusually large blooms of the diatom, *Rhizosolenia chunii*, in Port Phillip Bay, Australia in 1987–1988, initially resulted in a bitter taste in mussels, oysters and scallops (*Pecten alba*) (Parry et al. 1989). Abnormally high mortalities were noted in mussels and oysters, which were followed histologically during the post-exposure period. While scallops exhibited increased levels of mortality post-bloom, it is not clear whether these mortalities were caused by parasites, diseases or exposure to *R. chunii*.

In a more recent study, Chauvaud et al. (1998) suggested that large populations of a diatom, *Rhizosolenia delicatula*, could have led to reduction in feeding due to gill clogging, and cessation of growth in *Pecten maximus* in the Bay of Brest, France. In a later study of the same area, Lorrain et al. (2000) showed a decreased growth rate from 180 to 80 $\mu\text{m d}^{-1}$ in *P. maximus* associated with large blooms of *R. delicatula* and another diatom, *Ceratulina pelagica*. Again, they postulated that the reduction in growth rate was directly caused by the presence of these diatoms but no cause and effect was demonstrated and no laboratory studies accompanied the field work.

7.3 ENERGY UTILISATION: METABOLIC EXPENDITURE

Metabolic rate of bivalves, as measured by the rate of oxygen consumption (VO_2), is known to be influenced by a number of variables, including temperature, body size, oxygen tension, food concentration, salinity, reproductive state, activity level and physiological condition. The effect of salinity can be illustrated in *Argopecten purpuratus*, a euryhaline species, in which VO_2 increased with a decrease in salinity from 30 to 24 ppt, but declined with a further reduction in salinity from (24 to 18 ppt) (Navarro and González 1998). This pattern was similar to that observed for excretion rate (see section 7.4.1 on “Excretion and byssus secretion”).

The allometric relationship between body mass (tissue dry weight) and VO_2 has been determined for several pectinid species (Table 7.4). The coefficient (b) of this relationship varies between 0.486 and 0.986 [average = 0.75 excluding Vahl and Sundet (1985) values for reproductively mature individuals]. This mean value closely approximates that of 0.727 estimated for bivalves (Bayne and Newell 1983) and the value of 0.75 estimated for poikilotherms in general (Hemmingsen 1960). The biological significance of this parameter has been discussed by numerous authors (e.g., Zeuthen 1953; Hemmingsen 1960). A higher allometric coefficient (b) has been obtained in both larval and juvenile *Argopecten irradians concentricus* (Lu and Blake 1999), as has also been found for clearance rate. In juveniles (0.5 to 7 mm in shell height) the allometric equation is:

$$\text{VO}_2 (\mu\text{L O}_2 \text{ h}^{-1}) = 2.142 \times \text{AFDW}^{0.905} \text{ where AFDW in mg} \quad (3)$$

Table 7.4

Parameters of the allometric relationship between oxygen consumption (VO_2 ; $\text{mL O}_2 \text{ h}^{-1}$) and tissue dry weight (W ; g), following the equation $\text{VO}_2 = a W^b$, in several pectinids. (Unless specified, regressions were selected from seasons during which the animals are not at the peak of their reproductive development).

* Animals starved for 36 h prior to measurements.

⁺ Calculated from data in McLusky (1973).

This agrees with results by Riisgård (1998), who found that larval and early juvenile stages of bivalves are characterised by a higher exponent ($b = 0.9\text{--}1.0$) than larger animals ($b = 0.6\text{--}0.7$) and thus challenged the validity of a constant allometric exponent for VO_2 .

Metabolic rate (VO_2) is also highly responsive to food levels: VO_2 is markedly reduced to basal levels during starvation as in other bivalves (Grant and Cranford 1991), and in *P. magellanicus* at 10°C , VO_2 was found to be significantly higher (by 31%) at high food levels (ambient seston supplemented with cultured algae) than at low food levels (ambient seston) (Pilditch and Grant 1999b). Respiration rate was also significantly greater (by 36%) in *P. magellanicus* fed cultured phytoplankton compared to detrital diets containing fresh or aged kelp, or resuspended sediment (Grant and Cranford 1991). The increase in metabolic rate of feeding scallops is expected to be primarily associated with the post-ingestive costs of digestion and growth rather than the mechanical cost of filtration.

7.3.1 Metabolic Rate and Oxygen Availability

Aquatic organisms have been characterised as oxyregulators or oxyconformers depending on their ability to maintain a VO_2 independent of declining oxygen tension (PO_2) over some range of PO_2 values, or one that conforms (declines) with PO_2 . The critical oxygen tension (P_c) is given by the inflection point of the function relating VO_2 and PO_2 , beyond which VO_2 becomes dependent of ambient oxygen tension. A critical value of about 48–56% oxygen saturation was determined for *Pecten maximus* at 10°C (Brand and Roberts 1973), and a low value of ca. 20% for the oxyregulators *Argopecten irradians* and the deep sea scallop *Pecten grandis* (van Dam 1954). Other scallop species are poor oxygen regulators: in *Chlamys islandica* (Vahl 1972, 1978) and *Placopecten magellanicus* (Shumway, unpublished). VO_2 is independent of oxygen tension only to approximately 60–70% oxygen saturation, and in *C. delicatula* VO_2 declines gradually with decreasing oxygen tension, with no clear inflection point (Mackay and Shumway 1980) (Fig. 7.9). Similarly, in *Argopecten ventricosus* VO_2 remains independent of PO_2 only between 100 and 76% of oxygen saturation (Sicard et al. 1999 in Maeda-Martínez et al. 2000).

The qualitative distinction between oxyregulators and conformers has been criticised by Mangum and Van Winkle (1973), who point out that few species exhibit perfect regulation or strict oxyconformity over a wide range of external oxygen conditions, and that these conditions represent only extremes in a continuum. Bayne (1971) suggested the adoption of the ratio K_1/K_2 (where K_1 is the intercept, and K_2 is the slope of a plot of PO_2 against PO_2/VO_2) as a more relevant quantitative index of an organism's oxygen dependence. A relatively higher K_1/K_2 value indicates a reduced ability to regulate VO_2 . The response to declining oxygen tension of bivalve mollusks can vary with environmental conditions such as temperature and salinity (Shumway and Koehn 1982), nutritional condition, and body size (Shumway 1983). For example, Silva Loera (1986) found that small bay scallops, *Argopecten circularis*, (0.1 g in dry tissue weight) show a more marked dependency of VO_2 on PO_2 and therefore a higher K_1/K_2 ratio (565), than large individuals (1.0 g; $K_1/K_2 = 137.6$). In bivalve molluscs the relationship between the

Figure 7.9. The response of three oxyconforming pectinid species to declining oxygen tension (VO_2 = weight-specific oxygen uptake). Data for *Chlamys delicatula* from Mackey and Shumway 1980; *Pecten maximus* from Brand and Roberts 1974; *Placopecten magellanicus* from Shumway, unpublished data.

K_1/K_2 index and weight-specific VO_2 ($\text{mL h}^{-1} \text{g}^{-1}$) is described by an exponential equation. For the deep water scallop *Chlamys delicatula* (Mackay and Shumway 1980) this relationship is given by:

$$K_1/K_2 = 115.78 \times VO_2^{0.769} \quad (4)$$

The relatively high value of the constant in this equation ($= 115.78$) compared to other bivalves species again indicates that *C. delicatula* is a poor oxyregulator. *Artica islandica* is an extreme oxyconformer, as indicated by an intercept value of 1,000, whereas the mussels *Geukensia demissa* show intermediate values (76 and 63, respectively).

In scallops, as observed in other bivalves, variations in metabolic rate are generally reflected in changes in heart rate. In littoral molluscs, respiratory stress caused by sudden aerial exposure typically results in rapid bradycardia (reduction in heart rate) and valve

closure. On the other hand, *Pecten maximus* initially responds to air exposure by violent adductions of the shell and tachycardia, followed by gradual bradycardia, accompanied by wide gaping of valves. Inability to control air gaping and consequent vulnerability to desiccation is a characteristic feature of many sublittoral species including scallops (Brand and Roberts 1973). The inability to remain closed for extended periods of time also makes scallops highly vulnerable to low salinity stress (Stockton 1984; Tettelbach et al. 1985), especially at higher temperatures (Mercaldo and Rhodes 1982). Little is known, however, about the air-breathing capacity of scallops during emersion, which may occur naturally during stranding by storms, during seeding and shipping activities, or harvesting and return to the water of sublegal scallops (Duncan et al. 1994; Dredge 1997). *Pecten maximus* suffered respiratory acidosis and died after 72 h of emersion (Duncan et al. 1994). Acidosis was largely attributed to aerobic metabolism (CO_2 production) rather than accumulation of anaerobic end products. The decline in pH was not buffered by mobilisation of Ca from shell dissolution and resulting increase in HCO_3^- , as observed in intertidal bivalves that are more tolerant of emersion. Negligible survival of *Argopecten ventricosus* spat (3.5 mm shell height) was obtained after 26 h of air-exposure at temperatures ranging from 17 to 28°C (Maeda-Martínez et al. 2000). At a shorter exposure time (19 h) survival rate, measured after 2 h of re-immersion, was inversely related to temperature. Survival could be further enhanced during shipping by packaging animals tightly and thus preventing shell gaping, and by using pure oxygen. Predator avoidance response of juvenile *P. magellanicus* was not affected by 4 h air exposure at 18°C, but was adversely affected by the combined stress of air exposure and cold shock (18 to 8°C) (Lafrance et al. 2002). Thus both duration of air exposure and temperature (absolute value and change in temperature) are critical determinants of scallop survival during emersion.

A reduced capacity for oxyregulation, or increased VO_2 dependence on oxygen tension, may be a characteristic feature of species which are unlikely to experience low oxygen levels in their natural habitat (Bayne 1973). Scallops, as sublittoral, epifaunal bivalves, which are incapable of sustaining prolonged valve closure and are relatively intolerant of aerial exposure, are unlikely to experience low oxygen levels in the environment. In their analysis of 31 species of marine invertebrates, however, Mangum and Van Winkle (1973) found no correlation between the response of VO_2 to declining oxygen tension, and environmental oxygen level.

Hochachka and Somero (1984, Table 5–1) correlated the tolerance to anoxia in both terrestrial and aquatic organisms with the amount of glycogen stores, since glycogen is the main respiratory substrate during anaerobiosis. In this respect it is noteworthy that scallops, which are relatively intolerant of anoxia, contain relatively low levels of glycogen in the adductor muscle, the main storage organ (attaining maximum values of 23–25% of muscle dry weight in first-year *Argopecten irradians* (Epp et al. 1988) and 18% in *Chlamys islandica* (Sundet and Vahl 1981)). In contrast, *Mytilus edulis*, an intertidal bivalve that commonly utilises anaerobic pathways during prolonged valve closure induced by aerial exposure, attains high maximum seasonal glycogen levels of 42 to 53% in the mantle, the principle long term storage organ in mytilids (de Zwaan and Zandee 1972; Gabbott 1983).

7.3.2 Metabolic Cost of Reproduction

An increase in VO_2 associated with the metabolic cost of reproduction has been documented in the bay scallop, *Argopecten irradians irradians* (Bricelj et al. 1987b), giant scallop, *Placopecten magellanicus* (Shumway et al. 1988), Iceland scallop, *Chlamys islandica* (Vahl 1978) and black scallop *Chlamys varia* (Shafee 1982). Figure 7.10 illustrates the relationship between oxygen uptake, environmental temperature and gametogenic stage in three of these pectinid species. In contrast, MacDonald and Thompson (1986) found no significant correlation between oxygen uptake and gametogenic activity in *P. magellanicus* from Newfoundland populations at depths of 10 and 31 m. In bay scallops, gametogenesis (gonadal growth) was associated with a 50% increase in the routine rate of oxygen uptake relative to that predicted on the basis of seasonal temperature (Bricelj et al. 1987b). Vahl and Sundet (1985) found that sexually mature *C. islandica* have a higher size-specific metabolic rate during the period when they experience intense gamete differentiation, than immature scallops. For a scallop of comparable size (e.g., 0.8 g in tissue dry weight), the VO_2 of mature males and females is 57% and 70% higher respectively than that of immature scallops. They also found that the metabolic rate of sexually mature males increases at a faster rate with body size than that of mature females, and that for size classes greater than 1.2 g in tissue weight (ca. 50 mm in shell height) mature males have a higher metabolic rate than females. These authors suggest that the high cost of sperm production, involving protein synthesis, cannot be met by stored glycogen reserves, thereby restricting spermatogenesis to periods of high food availability (March to October), while oögenesis can continue throughout the fall and early winter at Balsfjord, Norway.

Bivalves typically show a pattern of increasing reproductive output with increasing age/size (Peterson 1983). Two pectinid species, however, the iteroparous *Chlamys islandica* (Vahl 1984), and the semelparous scallop *Argopecten irradians irradians* (Bricelj et al. 1987b, and Bricelj and Krause 1992), exhibit reproductive senility (*sensu* Peterson 1983) in that size-specific reproductive output declines in older individuals. Reproductive output declined in senescent *Placopecten magellanicus* from low food environments but was maintained in larger senescent scallops from adjacent higher food environments (MacDonald and Bayne 1993). The combination of seasonal availability of the food supply and the timing of the reproductive cycle permitted reproductive output to be maintained during a period of the life cycle when maintenance requires all the available resources. Fecundity was sacrificed for maintenance when food resources were limited but when food was more readily available fecundity in the large senescent individuals continued to increase (MacDonald and Bayne 1993). In the bay scallop, post-reproductive individuals approaching the end of their lifespan, exhibit a significantly lower weight-normalised VO_2 than young individuals which have not yet undergone reproduction (Bricelj et al. 1987b). Thus senescence is associated with lowered metabolic expenditure, as found for senescent gastropods *Ancylus fluviatilis* and *Planorbis contortus* (Calow 1975) and the limpet *Ferrissia rivularis* (Burky 1971).

Figure 7.10. Seasonal changes in oxygen consumption of three pectinid species in relation to environmental temperature and reproductive stage. Weight-normalised oxygen uptake of *Chlamys islandica* and *Placopecten magellanicus* from Vahl (1978) and Shumway et al. (1988), respectively. Reproductive stages of *C. islandica* from Sundet and Vahl (1981). Weight-specific oxygen uptake of *Argopecten irradians irradians* from Bricelj et al. (1987a).

7.3.3 Metabolic Rate in Relation to Temperature and Latitude

Spärck (1936) observed that scallop species with a more northerly distribution, e.g., the arctic scallop, *Pecten groenlandicus*, had a relatively higher VO_2 than those of southern latitudes, such as the boreal *P. varius* and Mediterranean *P. flexuosus*, when compared at the same temperature. Bricelj et al. (1987b) also found that the northern bay scallop, *Argopecten irradians irradians*, had a higher metabolic rate than the southern Florida subspecies, *A. i. concentricus* (Barber and Blake 1985), at a comparable temperature range (20–25°C). Since these two studies examined VO_2 at environmental temperatures, however, the possibility that the latitudinal differences observed simply reflect a lower degree of acclimatisation to higher temperatures in the northerly scallop population cannot be ruled out. In *A. i. irradians* seasonal changes in VO_2 closely track changes in temperature, which can explain 93% of the seasonal variation in metabolic rate (Fig. 7.10). In the southerly bay scallop, although oxygen uptake increases significantly with environmental temperature, the latter explains only 23% of the variation in metabolism (Barber and Blake 1985). The temperature range over which VO_2 was determined, however, was considerably narrower for the Florida population (21.5–31.7°C) than for the New York population (1.5–22.9°C). Barber and Blake (1985) suggested that the combined effects of lower food supply and higher temperature-dependent metabolic rates at lower latitudes may limit this species' southern distribution along the Atlantic coast.

A positive, significant correlation between VO_2 and both seasonal and laboratory acclimation temperature has been described in *Placopecten magellanicus* from Maine at a depth of 20 m (Shumway et al. 1988; Fig. 7.10). A strong correlation between VO_2 and ambient temperature was found in *P. magellanicus* from Newfoundland at 10 m, but not in those from 31 m (MacDonald and Thompson 1986). In *Patinopecten yessoensis* oxygen uptake closely tracks seasonal temperature changes, except during the winter months when weight-standardised VO_2 increases by 13% while water temperatures are still declining (5.8 to 4.6°C) (Fuji and Hashizume 1974). This period, extending between December and February, coincides with that of maximal gonadal growth, suggesting that the increase in metabolic rate is related to reproductive cost, as found in other scallop species. The above examples serve to illustrate that the degree to which seasonal changes in metabolic rate are determined by temperature can vary considerably both among pectinid species and within the same species.

In a unique study, Pilditch and Grant (1999b) compared the effects on VO_2 , NH_4^+ and growth rate of *P. magellanicus* exposed to a fluctuating temperature regime (6 to 15°C over an 8-day cycle, averaging 10°C) to those of scallops held at a constant temperature of 10°C. The fluctuating regime was intended to simulate the relatively high-frequency temperature changes occurring in coastal waters due to upwelling. They found a small (15%) but significant increase in VO_2 of scallops exposed to the fluctuating temperature treatment compared to those held at constant temperature, although this was not detected as a significant difference in growth of shell or total soft tissue dry weight. More importantly, they found no evidence of compensatory acclimation of sea scallops to

fluctuating temperatures, as VO_2 remained dependent on ambient temperature even after 48 days of exposure.

Shafee (1982) developed a predictive multiple regression equation for *Chlamys varia*, which allows calculation of the metabolic expenditure for this species at any time of the year. Oxygen consumption (VO_2 ; $\mu\text{L h}^{-1}$) was related to ambient temperature ($^{\circ}\text{C}$), tissue dry weight (W ; g), food supply (F), and reproductive condition (a) as follows: $\text{VO}_2 = (-89.92 + 23.37 T + 1,183.76 a + 134.47 F) W^{0.72}$ ($r^2 = 0.96$). Food supply was defined as $F = 0$ or $F = 1$, for starved and fed animals respectively. The gonad index was defined as the constant " a " in the allometric equation relating gonad dry weight (G) to total tissue dry weight ($G = aW^b$).

Seasonal Q_{10} values of oxygen consumption for several pectinid species are shown in Table 7.5. Values are typically >1 , indicating that most of the scallop species listed, unlike the blue mussel, *Mytilus edulis*, have a limited ability to acclimatise their metabolic rate to seasonal temperature changes, and are thus unable to conserve energy at higher temperatures. In *Chlamys varia* standard and routine oxygen uptake rates were temperature dependent ($Q_{10} > 2$), while active VO_2 (that of a starved animal suddenly exposed to food) showed a weak response to temperature ($Q_{10} = 1.0$) (Table 7.5).

7.3.4 Metabolic Rate in Relation to Activity Levels

Early work by Spärck (1936) indicated that bivalves capable of swimming such as members of the Pectinidae and Limidae families, were characterised by higher metabolic rates, as well as a greater increase in VO_2 with increasing temperature than other more sedentary bivalves of the Astartidae, Veneridae, and Tellinidae families. Van Dam (1954) however, reported VO_2 rates for *Pecten grandis* and *P. irradians*, which were within the range of values published for non-swimming boreal species.

Table 7.6 compares routine rates of oxygen uptake of pectinids with other bivalves at a common temperature (ca. 10°C). Values were carefully selected from studies in which animals were fed prior to measurements, a relatively wide size range was used, weight standardisation was carried out, and experimental animals were not experiencing rapid gonadal growth. Analysis of this table yields no evidence of increased metabolic rates in scallops when compared to a wide variety of more sedentary and sessile bivalves. Values shown, however, reflect metabolic rates of quiescent, undisturbed animals confined in experimental respirometers. They do not reflect active metabolic rates elicited during swimming or "clapping" activity of scallops. The cost of such activity cannot be incorporated in the energy budget of scallops without further understanding of its size and temperature dependence, and its contribution to overall energy expenditure. Decomposition of total metabolic rate into several functional components (Clarke 1987), partially achieved by measuring standard, routine and active metabolic rates (Bayne et al. 1976) has been carried out in considerable detail for *Mytilus edulis*, but has rarely been attempted for pectinids.

Limited information is available on the metabolic rate of scallops during locomotory activity, e.g., crawling of juveniles or swimming activity. Mackay and Shumway (1980) induced vigorous swimming of *C. deliculata* using starfish foot or extract, before placing

animals into respirometers. They found that the VO_2 of active animals was 2.4 times higher than that of resting (starved) animals, while feeding did not cause an increase in oxygen consumption above the standard rate of starved scallops. This observation was related to the fact that scallops are sublittoral, continuous feeders. An elevated VO_2 in response to feeding was suggested to be more typical of intertidal, discontinuous feeders such as *Mytilus edulis*. Swimming to exhaustion of *Chlamys hastata* confined within a respirometer, induced by contact with starfish, caused a significant, 3- to 4-fold increase in VO_2 (Donovan et al. 2003). On the other hand, seasonal temperature changes did not greatly influence the metabolic rate of *C. islandica*, and Vahl (1978) suggested that a significant portion (34%) of the seasonal variability in VO_2 in this population could be explained by changes in food availability. Oxygen uptake was also significantly correlated with food levels in both shallow and deep water populations of *Placopecten magellanicus* (MacDonald and Thompson 1986). In *Chlamys varia* routine VO_2 was on the average 1.6 to 1.9 times greater than standard oxygen uptake rates determined for starved individuals (Shafee 1982).

- D. *M. edulis* can acclimate its routine VO_2 between 10 and 20°C;
- E. Calculated by extrapolation from data at 5 and 15°C.

7.3.5 Anaerobic Metabolism

Bivalves may experience functional anaerobiosis (e.g., following vigorous activity such as burst swimming in scallops) or environmental anaerobiosis, as occurs under hypoxic or anoxic environmental conditions. Recent work has established that in many

bivalves, anaerobic metabolism can contribute significantly to the total metabolic rate, particularly in intertidal species, which suffer periodic aerial exposure (Pamatmat 1980; Shick et al. 1983). Therefore oxygen consumption does not always provide a reliable measure of total metabolism or heat loss as measured by direct calorimetry. Physiological and biochemical studies conducted on *Placopecten magellanicus* indicate that in scallops, anaerobic pathways are predominantly utilised for energy production during sudden bursts of activity (swimming or valve snapping escape response induced experimentally by predator stimulation) (Thompson et al. 1980; de Zwaan et al. 1980). Swimming activity is exhibited by members of at least four bivalve families: Pectinidae, Amussidae, Limidae and Cardidae. Scallops differ, however, from actively swimming bivalves such as the fileshell *Limaria fragilis* (family Limidae), which display slower sustained swimming activity fueled predominantly by aerobic mechanisms of ATP production (Baldwin and Lee 1979).

Scallops swim by means of jet propulsion in which water is expelled from the mantle cavity by repeated muscle contractions (valve snapping). This activity is powered by the phasic (striated or fast) portion of the adductor muscle, and to a lesser extent by the smaller catch or smooth portion, while more prolonged valve closure is exclusively powered by the catch muscle. Thompson et al. (1980) showed that in *Placopecten magellanicus* rapid shell valve adductions result in accelerated heart rate (2 to 3 fold increase), enhanced stroke volume and 5-fold increase in cardiac output, and a decrease in the PO_2 of post-branchial blood to a low value of 15 mm Hg. Although these physiological responses increase the supply of oxygen to the adductor muscle, they are insufficient to meet this organ's high energy demand during vigorous activity. The effectiveness of O_2 uptake by the scallops' blood (42% in *P. magellanicus*) and the supply of oxygen to the muscle are limited by the lack of respiratory pigments, and generally poor development of the bivalve open circulatory system. De Zwaan et al. (1980) suggested that different scallop species may vary in the relative contribution of aerobic and anaerobic metabolism to the total energy demand during swimming. In *P. magellanicus* these authors estimated that the former represents only 3% of the anaerobic contribution. However, due to the higher ATP yield of aerobic versus anaerobic glycogen utilisation, this translates into as much as 30% of the total ATP provided to the muscle by glycogen catabolism. The energy demand during valve snapping and the subsequent recovery phase is thus largely met by anaerobic glycolysis, and by the breakdown of high-energy phosphagen compounds (arginine phosphate, Arg P) in muscle tissue (arginine phosphate + ADP = arginine + ATP). The relative contribution of these two processes to the total energy demand during valve snapping varies between muscle parts, with phosphoarginine hydrolysis contributing most (72%) of the ATP requirement in the phasic muscle and only 34% in the catch muscle (de Zwaan et al. 1980).

The amino acid octopine is the main end product of anaerobic glycolysis accumulated in muscle tissue (both phasic and catch portions) as a result of exhaustive swimming and valve clapping in scallops (e.g., Grieshaber and Gade 1977; Baldwin and Opie 1978; Chih and Ellington 1983), as well as cephalopods, *Nautilus pompilius*, *Loligo vulgaris* and *Sepia officinalis*, and in *Cardium tuberculatum*, following vigorous jumping (reviewed by

Zandee et al. 1980). Octopine synthesis is catalysed by the enzyme octopine dehydrogenase (Odh) according to the reaction:

Other metabolic end products such as propionate and succinate are more typical of sedentary or sessile bivalves exposed to low oxygen tensions for prolonged periods. Breakdown of glycogen to octopine is associated with relatively low ATP yield per fuel equivalent (i.e., low efficiency of energy production) and rapid fatigue, but yields a relatively high rate of energy production or ATP output per unit time compared to propionate and succinate (Zandee et al. 1980; Livingstone 1991). Thus glycogen conversion to octopine is adaptive during temporary muscle anoxia associated with short term burst activity, such as swimming in scallops. Octopine production provides active marine molluscs (scallops, cephalopods) with an anaerobic pathway functionally analogous, although evolutionarily more primitive than that of lactate production, characteristic of vertebrates as well as many marine, freshwater and terrestrial invertebrates including gastropods (Livingstone 1991). Octopine production, however, differs from lactate production in that it results in a less acidic end product, has a lower energy yield, and requires an aminoacid (arginine) as well as carbohydrate as substrates.

Thus, swimming to exhaustion, induced experimentally by contact with starfish, caused a significant (~2-fold) increase in octopine levels, as well as a significant decrease in Arg P levels in the scallop *Chlamys hastata* (Donovan et al. 2003). In this study, encrustation of scallops with barnacles negatively affected their swimming capacity and resulted in increased anaerobic energy expenditure. Octopine levels of scallops exhausted by swimming were higher in encrusted than unencrusted scallops. The latter also consumed approximately twice as much Arg P as unencrusted scallops. In *Argopecten irradians concentricus* octopine production in the adductor muscle was restricted to periods of contractile activity (burst swimming) but did not occur during environmental hypoxia (Chih and Ellington 1983). Following 4 h of hypoxia there was a decline in Arg P and accumulation of succinate but no detectable octopine production.

A 5-fold increase in ODH activity in juvenile *Argopecten irradians* was related to a decrease in their percent attachment to the eelgrass canopy and thus increase in swimming activity between 6.7 and 29 mm SH (García-Esquivel and Bricelj 1993). On this basis, these authors proposed Odh activity as an index of the scallops' capacity for burst swimming activity. A significant positive correlation was described between the degree of individual multilocus heterozygosity and octopine accumulation after burst activity in *P. magellanicus* (Volckaert and Zouros 1989), and between heterozygosity and Odh and pyruvate kinase activities in the adductor muscle of the scallop *Euvola ziczac* (Alfonsi et al. 1995). In this context, Pérez et al. (2000) found that in *E. ziczac* the affinity of the Odh enzyme for pyruvate was greater in heterozygous than homozygote individuals at the Odh locus. These findings support the suggestion made by Volckaert and Zouros (1989) that the fitness advantage of heterozygosity in motile bivalves such as scallops may be related to their increased metabolic capacity for burst swimming involved in predator escape.

Repeated valve snapping can only be maintained for a few minutes and is followed by a period of apparent exhaustion, evidenced by the scallops' lack of response to further stimulation and valve closure. During this period blood PO_2 remains low, and scallops consume no oxygen, yet an increased heart rate is maintained. Thus recovery takes place under hypoxic/anoxic conditions. Utilisation of phosphoarginine and accumulation of octopine appear to occur more or less sequentially in scallops, the former providing the main energy source during initial valve snapping, and the latter accumulating mainly during later stages of swimming (Chih and Ellington 1983) or during recovery following exhaustion (Gäde 1980). Thus octopine formation serves primarily to replenish cytoplasmic NAD^+ required to maintain a high glycolytic flux (Baldwin and Opie 1978; Zandee et al. 1980). Upon reopening of valves, scallops exhibit a transient increase in VO_2 above normal, resting levels (Thompson et al. 1980). This increase probably reflects the repayment of an oxygen debt, i.e., the oxidation of anaerobic end products (octopine) accumulated in the tissues, although it could also reflect reoxygenation of the hemolymph. Restoration of physiological functions to resting values takes several hours in exhausted scallops. In adult *Argopecten irradians* a considerably shorter recovery period of 90 s was required before 100% of bay scallops tested experimentally could attempt a second swim following a prior swim, but the swimming distance was significantly shorter than on the first attempt, suggesting that full physiological recovery had not been achieved (Winter and Hamilton 1985).

Scallops do not normally experience prolonged periods of valve closure. However, Thompson et al. (1980) were able to induce valve closure in *Placopecten magellanicus* for up to 90 min by occasional tapping of the shell margin. Under these conditions, physiological responses differed from those elicited during valve snapping activity. The PO_2 of blood from the adductor muscle sinus remained relatively high (40 mm Hg), there was no increase in heart rate, and scallops continued to take up oxygen although at a reduced rate. Scallops are able to ventilate through the gape which occurs where the valves do not closely oppose each other. Thus although anaerobic pathways are invoked in the catch adductor, metabolism during valve closure remains largely aerobic. Furthermore, during valve closure phosphagen contributes less energy than anaerobic glycolysis to the total energy demand of the muscle, and octopine is no longer the sole end product of anaerobic metabolism, as observed during valve snapping (de Zwaan et al. 1980). Thus, both alanine and succinate were produced during valve closure.

A study using *in vivo* nuclear magnetic resonance to measure changes in phosphorus-containing metabolites showed that laboratory-induced hypoxia in juvenile *Placopecten magellanicus* collected in winter, when glycogen stores are low, caused a marked reduction in Arg P concentrations and intracellular pH, with an associated increase in inorganic phosphate (P_i) levels (Jackson et al. 1994), thus indicating a reliance on this phosphagen to meet the energy demands during environmental anaerobiosis. A similar response to hypoxia was observed in excised adductor muscle from adults, but was not apparent in live juvenile scallops collected in the summer. On this basis the authors suggested that changes in Arg P and P_i , or in the ratio Arg P/ P_i might provide a useful and more sensitive indicator of stress and energy status of scallops than the adenylate energy charge (AEC).

7.4 ENERGY UTILISATION

7.4.1 Excretion and Byssus Secretion

The excretion of nitrogenous excreta represents a potentially significant loss of energy in bivalves, particularly during conditions of severe nutritive stress when reliance on protein catabolism to support metabolic demand increases (Gabbott and Bayne 1973). Although ammonia is the major nitrogenous excretory product in bivalves, under certain circumstances dissolved organic nitrogen (primary amines) may comprise a significant fraction of total nitrogen excretion. In *Mytilus edulis* for example, the excretory loss represents up to 31% of the respiratory energy demand during the winter (calculated from Hilbish and Koehn 1985). At this time, amine and ammonia excretion contribute about 76 and 24%, respectively, to the total energy loss as nitrogenous excreta. Very limited data are available on excretion rates of nitrogenous products in pectinids. It is of particular interest to obtain information on the relative loss of primary amines and ammonia in this bivalve group, since several scallop species are known to rely heavily on protein catabolism during gametogenesis as well as during periods of negative energy balance (e.g., overwintering conditions) (Epp et al. 1988).

Ammonium excretion rates (VNH_4) have been determined for adult *Argopecten irradians concentricus* (Barber and Blake 1985), and are estimated to represent about 14% (range = 8.5 to 18.5%) of the respiratory energy loss. A similar contribution of VNH_4 to the respiratory loss (= 13.5%) was obtained for juveniles of this subspecies (Lu and Blake 1999). Ammonia excretion of adults increased significantly with decreasing salinity, a finding consistent with the role of excretory products (free amino acids) in cell volume regulation of bivalves (Deaton et al. 1984). Similarly, in *A. purpuratus* VNH_4 increased between 30 and 24 ppt, but declined with a further decrease in salinity (24 to 18 ppt), a range over which these scallops are physiologically impaired and show negative scope for growth (Navarro and González 1998).

The ratio of oxygen consumed to NH_4 - N excreted (O:N, calculated in atomic equivalents) was used in conjunction with respiratory quotients ($\text{CO}_2:\text{O}_2$) to identify seasonal changes in the dominant catabolic substrates in *A. irradians concentricus* (Barber and Blake 1985). Oxygen:N values, which ranged from about 6 to 22, were generally lower than those reported for mussels, *Mytilus edulis*. In this species values of 30 or below are generally indicative of a stressed animal with relatively high protein catabolism, and typically exceed 50 during periods of tissue growth (range = 17 to 120; Fig. 14 in Bayne and Newell 1983). In *Argopecten purpuratus* O:N values ranged between 9.5 and 32.6 over a salinity range of 30 to 18 ppt, showing a consistent decline with decreasing salinity in larger individuals (5 to 10 g dry soft tissue weight) (Navarro and González 1998). Values <15 were associated with unsuitable conditions for growth in larger scallops. There was also a negative relationship between scallop size and the O:N ratio, indicative of higher protein catabolism in younger individuals. In juvenile (57 mm SH) *P. magellanicus* exposed to varying experimental conditions (constant or fluctuating temperature regime; high or low food supply), O:N ratios ranged from 12 to 20 (Pilditch and Grant 1999b). In this study sea scallops showed positive shell and soft tissue growth

rates under all experimental conditions tested. A lower value of 8.9 was obtained for this species under thermal stress (Grant and Cranford 1991). Starvation of juvenile *P. magellanicus* yielded a C:N ratio of 12.7 compared to a value of 31 for scallops fed algal diets (Volckaert 1988 in Grant and Cranford 1991). Lower O:N ratios in scallops may be related to the more significant contribution of protein catabolism to the total energy metabolism in this group of bivalves (Epp et al. 1988) compared to *M. edulis*, which preferentially utilises glycogen stores to fuel gametogenesis (Gabbott 1975, 1983). Utilisation of the O:N ratio as a generalised index of physiological condition in scallops thus requires additional information on suitable reference values under normal as well as stressed conditions in each species.

Byssus secretion persists into the adult phase only in some pectinid species, such as *Chlamys islandica* and *C. opercularis*. In *Placopecten magellanicus* byssus formation (number of threads secreted) and rate of byssus attachment decline with increasing body size (Caddy 1972). The rate of byssus formation also increases with temperature, while percent attachment is temperature independent. The cost of byssus production as a function of scallop size/age has been determined for adult *Chlamys islandica* by measuring the energy content of byssal threads, which are composed mainly of quinone tanned protein (Vahl 1981). Byssus secretion represents only a minor component of the energy budget, ranging between 4 and 14% of somatic production.

7.4.2 Growth

Growth represents the integrated response of physiological processes of energy acquisition and expenditure detailed in the previous sections. Scope for growth and resource allocation between somatic and reproductive tissue production in pectinids are examined in a separate chapter (Thompson and MacDonald 1991; Chapter 8, this volume). Seasonal growth in bivalves, including pectinids, is influenced by the interaction of several environmental variables, particularly water temperature and food supply (e.g., Broom and Mason 1978; Bayne and Newell 1983). Food availability has often been found to exert a greater influence on growth rate than temperature in temperate scallop species (Orensanz 1984; MacDonald and Thompson 1985), as well as in species inhabiting regions of continually low temperatures, such as the subarctic scallop *Chlamys islandica* (Vahl 1978) and Antarctic scallop, *Adamussium colbecki* (Stockton 1984).

Scallops are generally very vulnerable to the effects of low salinities, as they are unable to maintain prolonged valve closure. In *Argopecten purpuratus* positive scope for growth (determined from physiological rate measures) was only obtained at 27 to 30 ppt. At lower salinities (24 to 18 ppt) scope for growth was negative as a result of the combined effects of reduced clearance and ingestion rates and high excretion and aerobic respiration rates (Navarro and González 1998).

In pectinids, intraspecific variability in growth rates and tissue weight for a given shell height has most frequently been correlated with differences in water depth. Scallops from inshore, shallower waters typically display higher growth rates and maximum sizes than those from deeper waters (*Placopecten magellanicus*: MacDonald and Thompson 1985; Schick et al. 1988; *Patinopecten caurinus*: Haynes and Hitz 1971; MacDonald and

Bourne 1987; *Pecten maximus*: Mason 1957; *Hinnites multirugosus*: Leighton 1979; see also Chapter 28 Lodeiros et al. this volume and Lodeiros et al. 1998). Depth *per se* is not the limiting factor, but, as demonstrated for *P. magellanicus* by MacDonald and Thompson (1985), growth is promoted by relatively higher temperatures and more importantly, higher food levels in shallow waters lying within the productive euphotic zone. For *Placopecten* from Canadian waters, differences in somatic weight between depths were more pronounced than differences in shell height. The negative correlation between maximum size and depth reported for many scallop populations thus supports Sebens' (1982) theoretical growth model, which predicts that maximum size attained by animals with indeterminate growth increases with habitat suitability (lower physiological stress).

Field experiments on the effect of depth on scallop growth convey mixed results. Comparisons between studies are complicated due to differences in species, starting sizes, stocking densities, gear, site, time of year and environmental conditions. Some reports document a decrease in growth with an increase in culture depth while others show no significant differences or even an increase in growth with depth. Côté et al. (1993) examined the influence of depth on the growth of juvenile sea scallops *Placopecten magellanicus* using pearl nets with 6-mm mesh and 0.16 m² bottom surface area. Nets were filled with 50, 100, 200, or 300 scallops (mean height 14.4 mm) and suspended from the surface at 9, 15, and 21 m. Growth, measured as dry mass of the shell, muscle and other soft tissues, tended to decrease with depth although the differences were only significant for soft tissue. At all depths, after 1 year, growth (measured as mean shell height) of scallops stocked at 50 individuals per net was significantly larger than of scallops stocked at 200 and 300 individuals per net. Focusing on *P. magellanicus* spat, Grecian et al. (2000) also evaluated the effects of culture depth. Four size classes (1.4–1.69 mm, 1.70–1.99 mm, 2.00–2.99 mm, ≥3.0 mm) of scallop spat were sorted and deployed in different types of nursery-based equipment including collector bags (1.2 and 2.0 mm) and pearl nets (1.5 and 3.0 mm) at two depths (5 and 10 m) for 10 months. Highest growth rates were found for the largest size class, in pearl nets and suspended in shallower waters. Rupp et al. (2004) examined depth and density effects on the lion's paw scallop, *Nodipecten nodosus*, in Southern Brazil. Postlarvae (0.4 mm) were deployed in collector bags at two densities (340 and 150 scallops/spat bag) at two depths (4 and 12 m) for 26–27 days. Growth rates were higher in shallower waters (4 m) during the summer (March–April) when South Atlantic Central Water (SACW) creates temperature and food quality differences with depth. In the winter (June–July), without SACW intrusions there were no depth related growth differences. Results from a computer model of the effects of depth and density on the growth of the Icelandic scallop, *Chlamys islandica* predict no effect of depth as long as no food limitation occurs (Fréchette and Daigle 2002). The model suggests that if food limitation occurs, growth rates would decrease with depth.

Emerson et al. (1994) also evaluated the effects of depth on the growth of *P. magellanicus*. Mesh cages (10 x 50 x 100 cm; 6-mm mesh) were filled with 100 juvenile scallops (mean shell height 39.7 ± 5.0 mm) and secured to a frame at 0, 20, 50, 100, or 200 cm above the bottom in approximately 7-m deep water. By the second period of the

growth experiment (October-November), scallops on the bottom had significantly larger shell heights than scallops at any other depth, but by the end of the experiment (March) it was determined that water depth had no consistent effect on shell height. Depth also had no significant effect on the ash content of soft tissues or the weight of the adductor muscle. The weight of soft tissues (excluding muscle) of scallops on the bottom was 40% less than that of scallops growing more than 50 cm off the bottom. Emerson et al. (1994) concluded that high seston concentrations near the bottom inhibited growth rather than providing an energetic benefit. Parrish et al. (1995) also reported that growth rates for *P. magellanicus* were similar over a range of depths. In this study, 200 scallops approximately 40 mm in shell height were ear hung on 1.2 x 1.2 m frames at 20, 50, and 300 cm above the bottom in 10-m water. Mean shell height (mm) and mean dry body mass (mg) were similar at all three depths over the course of the experiment (May-December) but appeared to be highest at 300 cm off the bottom during the latter part of the sampling period although the seston at that depth had the lowest concentration of microplankton, chlorophyll-*a*, AFDW and total lipids. Parrish et al. (1995) concluded that other factors than simply the availability of food, or high energy compounds are important to the growth of scallops. Kleinman et al. (1996), using *P. magellanicus* (mean shell height 22.2 ± 0.1 mm) compared growth in uncontained bottom cultures to growth in suspended pearl nets (100 scallops per net). During most months of the survey, significant differences were found between their three study sites for both culture methods. Although the average soft tissue condition index was significantly higher in the suspended cultures, shell growth rates, average adductor muscle condition index and average whole dry weights were all significantly higher for scallops in bottom cultures. Water temperature, total particulate matter, and chlorophyll concentration explained up to 66% of the variation in shell growth rates in suspended culture and up to 78% in bottom culture, and between 55% and 80% variation in soft tissue growth in suspended and bottom culture, respectively (Kleinman et al. 1996).

The depth at which pearl nets are suspended in the water column can also result in substantial growth differences for juvenile sea scallops. In an experiment, in which pearl nets were variously suspended from 5 m off-bottom to 0.25 m off-bottom, Dadswell and Parsons (1991) found that the mean size of juveniles ranged from 54 to 42 mm, respectively. Growth differences of this magnitude were similar to the effects of stocking density as determined by Parsons and Dadswell (1992). The effect of suspension depth on growth in sea scallops and other species of scallops has been attributed to differences in food level (Wallace and Reinsnes 1984, 1985; Côté et al. 1993). In a study contrasting an open and sheltered location in the Iles-de-la-Madeleines, scallop spat were found to grow and survive better in pearl nets that were grown near the surface (Gaudet 1994). Côté et al. (1993) found that spat grew better at 9 m than at 21 m and related this to the levels of food in the 0.7 to 5.0 μ m size range, although density effects masked some of the trends. From the above observations we can see there is likely no one depth that will be suitable in all locations. The optimum culture depth for a particular location will depend on the distribution of the food in the water column and the depth to which wave action will impact the suspended culture gear. There may also be interactions with other fouling species that may be depth dependent.

Intraspecific variation in growth between localities at similar depths has also been related to food limitation associated with high scallop densities (Gruffydd 1974; Orensanz 1984) and/or reduced flow (Cooper and Marshall 1963; Eckman 1987). Only a few studies have evaluated the effects of density on scallop growth. Côté et al. (1993) investigated the effects of stocking density on the growth of juvenile sea scallops *Placopecten magellanicus*. Using 6-mm mesh pearl nets with a bottom surface area of 0.16 m² and scallops with a mean shell height of 14.4 mm, nets were filled with 50, 100, 200, or 300 scallops and suspended from the surface at 9, 15, and 21 m. Growth, measured as dry mass of the shell, muscle and other soft tissues, decreased with increasing density but the differences were only significant between 50 and 300 scallops per pearl net. After 1 year, at all depths, the mean shell heights of scallops stocked at 50 individuals per net were significantly larger than of scallops stocked at 200 and 300 individuals per net. Using the same style of pearl nets, Côté et al. (1994) stocked 50, 75, 100, 150, 200, or 250 scallops (shell height 29.6 ± 0.3 mm) per net and anchored the nets 9 m above the bottom (approximately 15 m from the surface). In one set of nets all scallops were alive while in the other set of nets only 25 scallops were alive and the others were scallop shells glued together as “dummies”. After three months (July–October), at densities of 100 scallops/net and greater, mean growth rates of both shell and dry mass were always significantly lower in nets without dummies suggesting that the effects of density on growth were due to food limitations and not the lack of space. Growth models for Iceland scallops, *Chlamys islandica* also support the importance of food depletion on scallop growth (Fréchette and Daigle 2002).

The results for scallop spat are not as clear. Grecian et al. (2000) found no significant difference in growth rates between *P. magellanicus* spat (2.0–3.3 mm shell height) stocked at 2,600 and 5,200 scallops per collector bag deployed at 5-m for 8 months. They used “onion” collector bags, measuring 40 x 80 cm with a 3-mm nominal mesh size, filled with 1 meter of Netron®. The authors suggest that their relatively low stocking densities may not have created limitations of food or space for the spat. Also working with scallop spat, Rupp et al. (2004) examined the effect of density on the lion’s paw scallop, *Nodipecten nodosus*, in Southern Brazil. Postlarvae (0.4 mm) were deployed in collector bags at two densities (340 and 150 scallops/spat bag) at two depths (4 and 12 m) for 26–27 days. A slight, but statistically significant decrease in shell heights was observed at both depths for postlarvae stocked at the higher density.

Due to the high energetic cost of reproduction, shell and somatic tissue growth in pectinids may also be greatly influenced by reproductive events. Cessation or retardation of shell growth during the reproductive period (gonadal growth and spawning), and resumption of growth following spawning have been reported in *Argopecten irradians* (Bricelj et al. 1987a, Bricelj and Krause 1992), *Notovola meridionalis* (Fairbridge 1953) and *Patinopecten yessoensis* (Maru and Obara 1967), whereas shell and gonadal growth coincide in other pectinids such as *Chlamys opercularis* (Broom and Mason 1978) and *C. islandica* (Vahl 1978; 1981). In pectinids in which gametogenesis involves the utilisation of energy stores (reviewed by Barber, this volume), growth of somatic tissues may not follow the same pattern as shell growth, and is expected to be more strongly influenced by

the reproductive cycle than in species which meet their energy demand primarily from the external food supply.

Growth curves shown in Figure 7.11a, b, c illustrate the remarkable variability in growth rates, longevity and maximum size displayed by the Pectinidae. Shell growth has commonly been described by the von Bertalanffy model, and age information obtained from external growth rings in the shell. The largest scallop species, which attain asymptotic heights (H_{∞}) of up to 160–170 mm, are generally long-lived, with lifespans ranging between 18 and 23 years. These species are often characteristic of deeper waters (up to 100–200 m), such as *Chlamys islandica* (Vahl 1981), *Patinopecten caurinus* (MacDonald and Bourne 1987) and *Placopecten magellanicus* (MacDonald 1986; Schick et al. 1988), or of moderate depths (up to 50–60 m) such as *Pecten maximus* (Mason 1957) and *Crassadoma gigantea* (MacDonald and Bourne 1989). In contrast, species restricted to shallow coastal waters (<10 m) are generally characterised by shorter lifespans (2–8 years) and smaller asymptotic size. For example, *Argopecten irradians* reaches a maximum size of 80 mm at 2 years (Bricelj and Krause 1992), *Chlamys varia* attains ca. 54 mm at 7–8 years (Conan and Shafee 1978) and *C. tehuelcha* (H_{∞} = 83–91 mm) lives only about 6 years (Orensanz 1984).

Large size, protracted lifespan and deep water habitat are however, not always correlated with slow growth. The Bertalanffy growth coefficient (k) provides a measure of the rate of which animals reach their asymptotic shell height. The purple hinge rock scallop *Crassadoma gigantea* is slow growing, as reflected by its low k value (= 0.17) (MacDonald and Bourne 1989), while the giant Pacific sea scallop *Patinopecten caurinus*

grows fairly rapidly ($k = 0.39$) (MacDonald and Bourne 1987). A literature review of growth parameters for the giant scallop *Placopecten magellanicus* (Schick et al. 1988) provides an average k value of 0.24 ($n = 74$; $SD = 0.06$), which ranges widely between 0.17 and 0.38 depending on habitat suitability.

Finally, scallops grown in suspended culture generally achieve faster shell and somatic tissue growth rates, and a greater tissue weight and thinner shell for a given height than wild scallops of comparable age growing on the bottom (Ventilla 1982; MacDonald 1986; MacDonald and Bourne 1989). This agrees with the observation made earlier for natural scallop populations, that within a species, growth rate in shallow water is often greater than in deeper waters. In *Placopecten magellanicus* MacDonald (1986) showed that accelerated growth in above-bottom culture was also accompanied by a reduction in longevity and maximum size (from 174 to 128 mm in shell height). Thus, provided that fouling is controlled, enhanced growth of scallops suspended in surface waters results from the exploitation of more favourable seston and temperature conditions in the overlying water column relative to those present on the bottom (Leighton 1979; Wallace and Reinsnes 1985).

Chapter 8

Physiological Integrations and Energy Partitioning

Raymond J. Thompson and Bruce A. MacDonald

8.1 INTRODUCTION

In the Pectinidae, the measurement of shell growth rate has received a great deal of attention owing to its importance of fisheries management and aquaculture. There have also been numerous studies on reproductive cycles in several species of scallops to evaluate gametogenic activity and the time of spawning. However, much less emphasis has been placed on physiological energetics, which is concerned with the study of energy balance within individuals, not only in terms of the acquisition and expenditure of energy but also the efficiency with which it is converted from one form to another (Bayne and Newell 1983). This topic has recently been reviewed for marine molluscs in general (Bayne and Newell 1983) and for bivalves specifically (Griffiths and Griffiths 1987). In this chapter, we describe the influence of environmental factors on energy flow and the partitioning of energy within individuals and populations of pectinids. With the exception of some studies on two or three species, most investigators have not determined the amount of energy invested in somatic tissue growth or spent on gametes. The degree to which available resources are allocated to reproduction will strongly influence future form and function, including survivorship, fecundity and energy available for subsequent growth, yet until recently intraspecific variation in resource partitioning resulting from environmental influences has received little attention in scallops and has not been well understood.

8.2 ENERGY BALANCE, PHYSIOLOGICAL INTEGRATIONS AND THE PARTITIONING OF ENERGY BETWEEN GROWTH AND REPRODUCTION

8.2.1 Energy Budgets

The most common method of assessing energy balance in an individual organism is to measure the components of the energy budget equation where:

$$C = P + R + F + U \quad (1)$$

The primary source of energy is food consumption (C), whereas energy expenditures include faecal losses (F), excretory products (U), respiratory heat loss (R) and energy invested in production (P) (Vahl 1981a; Bayne and Newell 1983). By rearranging this equation it is possible to calculate several parameters relevant to energy balance,

particularly absorbed ration $AB = C - F$ or $AB = C \times AE$, where AE is absorption efficiency. The proportion of energy potentially available for physiological activity is referred to as the assimilated ration A and is given by $A = AB - U$ or $A = R + P$. Assimilated energy is used to support the requirements of routine and active metabolism (i.e., respiration R), the remainder being available for production (P).

Fuji and Hashizume (1974), working on the Japanese scallop *Patinopecten yessoensis*, provided some of the earliest information on energy balance in marine bivalves, and combined seasonal measurements of growth, respiration and faecal production to illustrate energy flow through young scallops. In their study and many others on bivalves, no distinction was made between absorbed and assimilated ration, because bivalves are primarily ammonotelic and nitrogenous losses usually represent a small component of the total budget, e.g., Less than 5% in the giant scallop *Placopecten magellanicus* (MacDonald and Thompson 1986a). Excreted nitrogen, however, may constitute a significant metabolic loss for some species, such as the blue mussel *Mytilus edulis*, under certain conditions (Bayne and Scullard 1977). More than half of the assimilated energy in young *Patinopecten yessoensis* and *Choromytilus meridionalis* (black mussel) is used to meet metabolic requirements, the remainder being divided almost equally between soft tissue growth and gamete synthesis (Fuji and Hashizume 1974; Griffiths 1981a).

8.2.2 Scope for Growth

An organism can only allocate energy to growth or reproduction while it remains in positive energy balance i.e., if absorbed ration exceeds total metabolic losses. If the latter exceed the former, then energy reserves are utilised for maintenance purposes (Newell 1979). The energy available for production after respiration and excretion have been subtracted from absorption [$AB - (R + U)$] is referred to as scope for growth (Warren and Davis 1967; Bayne and Newell 1983; Griffiths and Griffiths 1987), which in a bivalve is the physiological equivalent of the sum of reproductive output, somatic tissue growth and shell production. Scope for growth is often measured in short term laboratory studies to predict the response of the whole organism to a variety of conditions in the natural environment, and there has been reasonable agreement between growth predicted from physiological measurement (scope for growth) and growth determined directly (Dame 1972; Bayne and Worrall 1980). A better understanding of the physiological mechanisms which ultimately influence energy balance in pectinids will require measurements of the integrated response (scope for growth) under natural temperature and food conditions.

8.2.3 Growth Efficiency and Turnover Ratio

The efficiency with which food ration is converted to production (P/C) is referred to as total gross growth efficiency, whereas the proportion of absorbed ration converted to production (P/AB) is termed total net growth efficiency. Production of somatic tissue alone as a fraction of ingested ration (Pg/C) and absorbed ration (Pg/AB) are referred to as

gross and net somatic growth efficiency respectively. Not only do these efficiencies vary with age but they may also fluctuate in response to changes in the environment.

The ratio of production to biomass (P/B), also known as the turnover ratio, has been widely used to estimate the production of natural populations from biomass estimates when mortality, growth or age composition are unknown (Banse and Mosher 1980), and has also been employed to compare energy flow through different populations in relation to the standing stock. It is important to distinguish biomass, which is an accumulated quantity of mass or energy, from production, which represents the rate of incorporation of organic matter or energy into the tissues (Davis 1963; Crisp 1984). In this review we shall discuss turnover ratios for individual scallops as well as for populations, and where appropriate we shall also take into account the reproductive component of production. Many of the P/B values recorded in the literature are based on somatic production rather than total production (Warwick 1980).

8.2.4 Growth of Shell and Somatic Tissue

In many studies, growth in bivalves has been described in terms of an increase in some dimension of the shell, usually length, the maximum distance between the anterior and posterior margins (Seed 1980). For the Pectinidae, shell height, which is the maximum distance between the dorsal (hinge) and ventral margins, has frequently been substituted for length. Growth rate may be expressed as an increase in size per unit time (usually years), i.e., the absolute growth rate, or as a proportional increase per unit time, i.e., the relative growth rate (Seed 1976). The rate of change in one variable relative to another, e.g., shell volume to shell length, has also been used to describe growth rates using allometric equations. The most popular method of describing growth, however, is to establish the relationship between shell size and age in order to construct a growth curve, which is often fitted to a non-linear mathematical function such as the von Bertalanffy model for predicative comparative purposes. In order for such models to be used effectively it is essential that certain criteria be met, including representation from all age classes, especially the youngest ones, and that the limitations and significance of the parameters should be recognised. For example, the parameter K, or Brody growth coefficient, is not a measure of absolute growth rate *per se* but rather an indicator of relative growth, representing the rate at which the asymptotic size is attained.

The majority of studies describing growth in pectinids have dealt exclusively with growth rates of the shell, but in order to measure production and energy flow it is necessary to record the weight of the soft tissue. Body weights are then converted to energy equivalents after biochemical analysis. Short-term variation in tissue weight is not always reflected in a change in shell dimensions, e.g., in the mussel *Mytilus edulis*, in which shell and somatic growth are not necessarily seasonally coupled (Hilbish 1986). Shell growth may continue throughout the entire lifespan in long-lived pectinids, whereas growth of the soft tissues of the soma often ceases completely and may become negative (Vahl 1981a; Macdonald and Thompson 1985a). Short-term variation in somatic tissue weight or energy content is a more sensitive indicator of growth fluctuations within the

individual than is a change in shell dimensions, because unlike the soft tissue the shell cannot shrink rapidly under adverse environmental conditions e.g., in *Placopecten magellanicus* (Macdonald and Thompson 1985a). For describing the growth of shell or soft tissue, polynomial equations provide an alternative to the non-linear models such as the von Bertalanffy, and possess the advantage of not imposing asymptotic behaviour (Roff 1980), as well as being easier to deal with statistically when making comparisons between groups. The disadvantage of the polynomial is that the coefficients have no biological significance, unlike the parameters of the von Bertalanffy function. MacDonald and Thompson (1985a) found that shell growth in *P. magellanicus* was described well by a von Bertalanffy treatment, whereas a polynomial was required for the analysis of somatic growth, owing to the lack of an asymptotic weight as a result of the resorption of somatic tissue in senescent individuals. The selection of an appropriate model to fit a growth curve will largely depend on the properties of the data.

8.2.5 Reproductive Effort

Physiological indices such as the scope for growth afford one means by which the response of the whole organism to environmental change may be described, but a useful alternative is to establish the partitioning of assimilated energy between growth and reproduction. Of particular significance is the reproductive effort, defined as that proportion of the energy available to the individual which is channelled into reproduction. Approximately twenty years ago considerable interest arose among life history theorists in the concept of reproductive effort as a fitness correlate, and in the last decade several workers have responded to the challenge of producing empirical data to test some of the demographic theory. Estimates of reproductive effort have now been made for a variety of organisms from diverse taxa, and included experimental observations as well as determinations for natural populations. In many instances the objective in measuring reproductive effort has been to provide an insight into the ecology of the species or population rather than to test the predications of life-history theory. There is now a considerable body of data dealing with the reproductive energetics of bivalve molluscs (reviewed by Bayne and Newell 1983; Griffiths and Griffiths 1987), and much of this work has been undertaken on four pectinid species, the Iceland scallop *Chlamys islandica* (Vahl 1981b), the black scallop *Chlamys varia* (Shafee and Lucas 1982), the giant or deep-sea scallop *Placopecten magellanicus* (MacDonald 1986; MacDonald et al. 1987; MacDonald and Thompson 1988) and the weathervane scallop *Patinopecten caurinus* (MacDonald and Bourne 1987). For other pectinids, notably the bay scallop *Argopecten irradians*, information is available on reproductive output and the production of adductor muscle tissue (Bricelj et al. 1987a) but the absence of data sets containing both gamete production and total production of somatic tissue precludes any analysis of reproductive effort.

The measurement of reproductive effort presents some difficulties. There are two approaches which can be taken, both of which require an estimate of reproductive output, usually obtained by the weight loss on spawning. The first procedure is to express reproductive output as a proportion or percentage of total production by the individual, for

which the somatic component is generally determined from the annual increment in tissue weight for each age class. Thus we have $RE = Pr/(Pg + Pr)$, where Pr is gamete production and Pg is somatic production over the same time period (usually one year). If significant, the production of organic material such as conchiolin deposited in the shell matrix (Ps) should be included in the denominator. When appropriate, byssus production (Pby) may also be considered (Vahl 1981a; Shafee and Lucas 1982). Data for weight are usually converted to common energy units. This is a useful means of calculating reproductive effort when the ages of individual animals can be determined, as in many scallop species, and is particularly relevant ecologically, since it considers the partitioning of energy by the organism in terms of net production.

In the second approach, suggested by Hirshfield and Tinkle (1975) and developed largely by Calow (1978; 1979), reproductive effort is derived by relating gonad output to some measure of energy input, so that $RE = Pr/I$, where I is absorbed ration, or $RE = Pr/(I - R)$, where R is metabolic rate. Other authors (e.g., Vahl 1981b) have proposed various alternatives based on these fundamental equations. Such physiological indices have proved particularly useful in experimental work in which food ration is controlled (Calow and Woollhead 1977; Thompson 1983), because they do not depend on the determination of somatic growth over long periods. In field studies, however, it is usually too difficult or time consuming to measure food availability, ingestion rate, absorption efficiency and metabolic rate under natural conditions, and the physiological approach to the measurement of reproductive effort is rarely adopted. There are, nevertheless, three studies on natural populations of bivalves (including two pectinid species) in which both the physiological and the production methods have been used (Vahl 1981b; Bayne et al. 1983; Macdonald et al. 1987). In each study the two indices of reproductive effort showed similar trends.

Other alternatives for the estimation of reproductive effort have been employed, particularly the expression of gamete production as a proportion of body weight. This is an attractive option because it circumvents the necessity of measuring somatic production, for which a more convenient quantity (biomass) is substituted, but it can lead to serious underestimates of reproductive effort, especially in long-lived species, because reproductive output in a single year is divided by somatic production accumulated over several years. The procedure is of limited use in comparative studies. Some authors have also used reproductive output as an index of reproductive effort, which has led to unnecessary semantic difficulties and has contributed to the lack of a general understanding or agreed definition of the latter term. Although there is usually a positive correlation between reproductive output and effort, there are circumstances in which a reduction in reproductive output is associated with enhanced reproductive effort, especially during poor conditions (Hirshfield 1980; Thompson 1983). In this review we shall use the term reproductive effort to refer only to those indices in which gonad production is expressed in terms of total production ($Pr + Pg$) or of some estimate of energy input into the organism (e.g., I or $I - R$).

8.3 CHANGES RELATED TO AGE OF INDIVIDUALS

8.3.1 Scope for Growth

Very little information exists on variation in scope for growth as bivalves get larger or older. In the mussel *Aulacomya ater*, smaller individuals gain more energy than larger ones at the same food ration because the latter must expend a greater proportion of their absorbed energy to offset metabolic costs (Griffiths and Griffiths 1987). According to MacDonald and Thompson (1985b, 1986a), annual gamete production, assimilated energy and respiratory losses are increasing functions of age in the giant scallop *Placopecten magellanicus* (Fig. 8.1a). These curves were derived by combining physiological measurements (metabolic expenditure, clearance rate, absorption efficiency and energy content of the natural seston) for each month of the year to obtain an estimate of cumulative annual scope for growth (A - R). Unlike instantaneous estimates of scope for growth, which are often greater for smaller individuals than for larger ones, cumulative annual values increase with age for the first five years of life, after which scope remains constant. This is consistent with direct measurements, which demonstrate that annual production in a 15-year old scallop is almost twice that of a five-year old. When expressed in terms of energy per unit body weight, however, annual cumulative scope for growth decreases with age (Fig. 8.1b). In the population of *P. magellanicus* studied by MacDonald and Thompson (1986a,b), scope for growth underestimated measured production by about 25–60% in scallops from shallow water, whereas in those from deeper water the predicted values (not shown) exceeded measured production by approximately the same amount.

8.3.2 Growth Efficiency and Turnover Ratio

Gross and net somatic growth efficiencies for *Placopecten magellanicus* (MacDonald and Thompson, unpublished), together with net somatic growth efficiencies for *Chlamys islandica* (Vahl 1981a), are presented in Fig. 8.2. Both species invest similar percentages of the absorbed ration in somatic growth, although this may vary between populations. As scallops grow older an increasing amount of assimilated energy is required to support respiratory demands, and more of the non-respired assimilation is spent on reproduction, resulting in decreased growth efficiencies.

Data for *Chlamys varia* (Conan and Shafee 1978; Shafee and Lucas 1980, 1982) and *Placopecten magellanicus* (MacDonald and Thompson 1985b; 1988) confirm the generally held view that the turnover ratio decreases with age, indicating that older individuals are less productive per gram of body tissue than younger individuals (Fig. 8.3). When total production (Pt) rather than somatic production (Pg) is used as the numerator, the P/B ratio may become independent of age in the last few age classes, despite increasing body mass (Fig. 8.3). This is because reproductive output often continues to increase throughout the lifetime of the scallop, whereas somatic production remains constant or declines in older individuals (MacDonald and Thompson 1985b; 1988).

Figure 8.1. (A) Scope for growth per scallop compared with measured production (P_t) in the giant scallop *Placopecten magellanicus*. Scope = $A - R$, where A is assimilated ration and R is respiratory loss. (B) Scope for growth per gram of dry tissue (less shell). Data from MacDonald and Thompson (1985b; 1986a).

8.3.3 Somatic Growth and Maximum Size

The growth rate of an individual is the product of resource availability and the efficiency with which it is converted into body tissue (Calow and Townsend 1981). Relationships between the rates of feeding or oxygen uptake and body size are often described using the allometric equation $y = aW^b$ where a and b are fitted parameters, W is body weight and y is the predicted rate. The exponent (b) for respiratory energy loss is usually higher than the exponent describing energy gain from feeding (Bayne and Newell 1983). This results in a reduction in the energy available for growth as the organism increases in size, and provides a physiological basis for the decrease in growth by older individuals (Sebens 1979). Another factor which contributes to a decrease in somatic growth with increasing age is the gradual redistribution of this available energy to favour gamete production rather than growth as the animal becomes larger (see "Somatic

Figure 8.2. (A) Gross growth efficiency P_g/C (where P_g is annual somatic production and C is annual food intake) in giant scallops *Placopecten magellanicus* from 10 m and 31 m depths at Sunnyside, Trinity Bay, Newfoundland. (B) Net growth efficiency P_g/AB (where AB is the absorbed ration over one year) in *P. magellanicus* from 10 m and 31 m at Sunnyside, and in *Chlamys islandica* from Balsfjord, Norway. Data from MacDonald and Thompson (unpublished) and Vahl (1981a).

production and reproductive output"). According to Bayne and Newell (1983) and Bayne (1984) it is this process which may ultimately set the limit on size. Although smaller individuals are more efficient in acquiring energy relative to their metabolic expenses than are larger ones, this advantage is partially offset by associated disadvantages such as a higher maintenance ration per unit body weight, a more rapid weight loss during starvation and a higher predation pressure (Bayne 1985; Paine 1976).

8.3.4 Somatic Production and Reproductive Output

Most of the studies on reproductive energetics in bivalves demonstrate that gonad output P_r increases as the animal becomes older, whereas somatic production P_g reaches a maximum early in life and remains constant or declines thereafter (Bayne and Newell

Figure 8.3. Turnover ratio (production: biomass ratio) for individual black scallops *Chlamys varia*. P_g is somatic production, P_t total production, and B mean biomass. Data from Conan and Shafee (1978), Shafee and Lucas (1980; 1982).

1983; Griffiths and Griffiths 1987). Certain long-lived pectinid species, such as *Placopecten magellanicus* and *Chlamys islandica*, are ideal for such studies, especially since the age of an individual can often be determined by counting annual growth rings on the shell or the ligament. Thus in one population of *Placopecten magellanicus* studied by MacDonald and Thompson (1985b), P_g increased with age until it peaked at approximately five years, after which P_g fell steadily (Fig. 8.4a). In senescent individuals, P_g became negative i.e., somatic tissue was resorbed, a phenomenon which has been recorded for *Chlamys islandica* (Vahl 1981c) and other aquatic invertebrates (Calow and Woollhead 1977) but does not seem to be general. In *Placopecten magellanicus* P_r was very low in young individuals but gradually increased throughout the life of the scallop (Fig. 8.4a), so that eventually almost all the surplus energy was spent on gametes. The same trends have been observed in other populations of the giant scallop (MacDonald and Thompson 1985b; 1988; MacDonald 1986; Langton et al. 1987), and similar relationships among P_g , P_r and age have been described for various pectinids (see Figs. 8.4b, 8.5a, 8.6a), including *C. islandica* (Vahl 1981a), *Patinopecten caurinus* (MacDonald and Bourne 1987), and *C. varia* (Shafee and Lucas 1982). Maximum P_r exceeded maximum P_g in *Placopecten magellanicus* by at least a factor of two, but they were approximately equal in *C. islandica* (Fig. 8.4). Iceland scallops appeared to mature later than giant scallops, and in the former P_r did not become a detectable part of production until the scallops were at least five years old. Nevertheless, the transition from an emphasis on growth to enhanced reproduction occurred at approximately the same age (7–8 yrs) in both species. Shell production P_s was in low *Placopecten magellanicus* (Fig. 8.4a) and *Patinopecten caurinus* (Fig. 8.5a), but relatively high in young individuals of the short-lived *C. varia* (Fig. 8.6a). In *Patinopecten caurinus* and *C. varia* P_s decreased with age, but no clear trend was observed in *Placopecten magellanicus* or *C. islandica*.

Figure 8.4. Somatic production (P_g) reproductive output (P_r) and shell production (P_s) in (A) the giant scallop *Placopecten magellanicus* (B) the Iceland scallop *Chlamys islandica*. Data from MacDonald and Thompson (1985b) and from Vahl (1981a).

8.3.5 Reproductive Effort

These age-related changes in P_g and P_r in several species of scallops are reflected in an increase in reproductive effort as the individual grows older (Figs. 8.5b, 8.6b, 8.7). This has been demonstrated in *Placopecten magellanicus* (MacDonald 1986, MacDonald et al. 1987, Langton et al. 1987, MacDonald and Thompson 1988), *Patinopecten caurinus* (MacDonald and Bourne 1987), *Chlamys islandica* (Vahl 1981b) and *C. varia* (Shafee and Lucas 1982), as well as in other bivalves (Bayne and Newell 1983; Griffiths and Griffiths 1987). Reproductive effort (expressed as $100 \times P_r / (P_g + P_r)$) is usually high in old individuals and may approach 100% in senescent animals of some species, e.g., *Patinopecten caurinus* and *Placopecten magellanicus* (Figs. 8.5, 8.7). Thus, there is a gradual transition from an early phase in which growth is favoured to a later phase in which reproductive output greatly exceeds somatic production. This may be a result of selective pressure for early increase in size as a refuge from predation (Paine 1976), coupled with selection for high fecundity (i.e., greater fitness) in larger individuals.

Figure 8.5. Somatic production (P_g), reproductive output (P_r), shell production (P_s) and reproductive effort in offshore and inshore populations of the weathervane scallop *Patinopecten caurinus* from British Columbia. Data from MacDonald and Bourne (1987).

Figure 8.6. Somatic production (P_g), reproductive output (P_r), shell production (P_s) and reproductive effort in the black scallop *Chlamys varia* during two consecutive years. Data from Shafee and Lucas (1982).

The data for scallops and other bivalves are consistent with most life-history theory, which predicts that reproductive effort should increase with age in species which experience low mortality in the reproductive phase and which continue to grow after maturation (Charlesworth and Leon 1976; MacDonald et al. 1987).

8.4 ENVIRONMENTAL INFLUENCE ON PRODUCTION

8.4.1 Scope for Growth and Growth Efficiency

Any environmental factor that alters the rates of ingestion, absorption, excretion or oxygen uptake will influence scope for growth in either a positive or negative fashion. The blue mussel *Mytilus edulis*, for example, is capable of remaining in positive energy balance over a wide temperature range (5–20°C), whereas the European oyster *Ostrea edulis* is not (Widdows 1978; Newell et al. 1977). Scope for growth in *M. edulis* and *Aulacomya ater* fed with algal cultures increases with cell concentration until absorption efficiency declines, eventually resulting in negative value for scope (Bayne and Newell 1983). The relationship between scope for growth and the availability of seston to natural populations of bivalves is much more complex, owing to the production of pseudofaeces, fluctuations in food quality, and the difficulty in estimating absorption efficiency.

Figure 8.7. The relationship between reproductive effort and age in several populations of the giant scallop *Placopecten magellanicus*. Modified from MacDonald and Thompson (1988) and MacDonald et al. (1987).

Seasonal values of scope for growth in scallops feeding on natural seston at ambient temperature have been reported for *Placopecten magellanicus* from a population in Newfoundland (MacDonald and Thompson 1986a). Scope was lowest during the winter, often approaching zero or becoming negative, and maximum values were observed in May ($\approx 1^\circ\text{C}$), August and September (12°C) when food was abundant (Fig. 8.8). The excess energy available in May was spent on gamete production rather than somatic growth, because somatic weight actually decreased during this period. Small scallops were almost always in positive energy balance and had the potential to grow or synthesise gametes throughout the year, whereas the largest scallops may only have been capable of significant growth or gamete production in a few months of the year. Similar seasonal trends in scope for growth have been reported for other bivalve species, such as *Chlamys islandica* (Vahl 1980), *Mytilus edulis* (Bayne and Widdows 1978; Thompson 1984a) and *Mya arenaria* (Gilfillan et al. 1976), although *Mya arenaria* apparently does not take advantage of the abundant food supply during the spring bloom in March. The combined effects of ration and temperature on energy balance are considerable, ration often being the most influential single factor (Bayne and Newell 1983).

Figure 8.8. The seasonal cycle in scope for growth per unit dry weight of soft tissues in the giant scallop *Placopecten magellanicus* from 10 m and 31 m depth at Sunnyside, Trinity Bay, Newfoundland. (A) scallop of dry tissue weight 5 g. (B) scallop of dry weight 30 g. Modified from MacDonald and Thompson (1986a).

Estimates of growth efficiency based on physiological measurements have been made for *Chlamys islandica* (net efficiency; Vahl 1981a) and for two groups of *Placopecten magellanicus* from different water depths at one location (gross and net efficiencies; MacDonald and Thompson 1986a; b). Although ingested ration for larger *P. magellanicus* was greater in scallops from the more favourable shallow water environment than in those from deeper water, there were no differences between groups in the proportion of ingested or of absorbed ration which was invested in somatic production at any given age (Fig. 8.2).

8.4.2 Growth of Shell and Somatic Tissue

The influence of environmental conditions such as food availability and ambient temperature on growth and production has been the central theme of many studies on marine bivalves. The aim of such studies has often been to understand how a species contributes to energy flow in the ecosystem, or to evaluate the suitability of habitats for species under consideration for mariculture. The approach often adopted has been to compare individuals collected from various points along an environmental gradient over which food and temperature conditions may be expected to vary, such as the intertidal zone, different water depths, polluted habitats or sites separated geographically. Although food ration has been recognised as the major factor regulating growth and production, very few studies have actually quantified the food resources available to suspension feeders at various times of the year (Bayne and Newell 1983). In the few studies in which seston has been measured, growth rates have been well correlated with food availability for *Mytilus edulis* (Rodhouse et al. 1984, Page and Hubbard 1987), *Placopecten magellanicus* (MacDonald and Thompson 1985a), *Macoma balthica* (Hummel 1985; Thompson and Nichols 1988) and *Crassostrea gigas* (Brown 1988).

In populations of *Placopecten magellanicus* from shallow water habitats in southeastern Newfoundland, better food and temperature conditions are reflected in faster shell and somatic growth rates (Fig. 8.9). Somatic growth (less shell) is more sensitive to environmental conditions than is shell growth, the environmental effects being more evident in the somatic growth curves than in those for the shell. In the Bay of Fundy, however, scallops from deep water do not grow more slowly than those from shallow water, probably because the water column is vertically mixed and the food supply more uniformly distributed (MacDonald and Thompson 1985a). Local oceanographic conditions determine whether growth declines with increasing water depth. Not only do scallops from shallow water environments in Newfoundland often grow faster but they also reach a much greater asymptotic height and maximum somatic weight. Somatic weight actually decreases in the oldest individuals, a phenomenon which is revealed by fitting a polynomial but is obscured by the forced asymptote if the more traditional von Bertalanffy equation is used. Maximum size is reached when energy input from feeding equals metabolic losses, so that there is no surplus energy available for further growth. These findings are consistent with Sebens' (1979; 1982; 1987) theoretical growth model that predicts an increase in asymptotic size if ration is increased or metabolic demand

Figure 8.9. Growth curves for the giant scallop *Placopecten magellanicus* from 10 m and 31 m depth at Sunnyside, Trinity Bay, Newfoundland. (A) shell growth fitted by the von Bertalanffy model. (B) somatic tissue growth fitted by a polynomial, the dashed lines showing the asymptotes that would be produced by a von Bertalanffy equation. Modified from MacDonald and Thompson 1985a).

decreased (Fig. 8.10), and they provide evidence for the role of ration in establishing the maximum size which the scallop may attain in any particular environment.

Whereas the majority of studies have concentrated on annual growth, others have been concerned with the growth rates or physiological condition of individual animals at different times of the year. The instantaneous growth rate is dependent upon seasonal cycles of food availability, water temperature and possibly gametogenesis. A great deal of energy is required for the production of gametes in marine bivalves, which often results in close coupling between the reproductive cycle and the energy available for growth (Bayne 1985). In *Macoma balthica*, somatic tissue growth and gamete development often occur simultaneously, with food availability limiting growth in some months, depending upon the location of the year (Thompson and Nichols 1988). In *Argopecten irradians*, most adductor muscle growth takes place in the autumn after gamete development and spawning in spring/summer (Bricelj et al. 1987a). Gamete development in the bay scallop sometimes requires the utilisation of stored muscle reserves, although in some locations ambient food resources are adequate (Bricelj et al. 1987b). In *Placopecten*

magellanicus from southeast Newfoundland, gametogenic activity proceeds very rapidly in the spring as food availability and temperature increase simultaneously (MacDonald and Thompson 1986a). Somatic weight decreases as the gonad grows during gametogenesis, although outside the reproductive period the giant scallop is capable of growing in any month despite very low temperatures (Fig. 8.11).

Figure 8.10. Somatic growth curves (polynomials) for giant scallops *Placopecten magellanicus* from various depths at Sunnyside, Trinity Bay, Newfoundland in different years. The dashed line joins points on each curve at which somatic weight is either a maximum or becomes asymptotic. Modified from MacDonald and Thompson (1985a).

Figure 8.11. Seasonal changes in dry weight of the somatic tissue and the dry weight of gametes in the gonad for the giant scallop *Placopecten magellanicus* from 10 m depth at Sunnyside, Trinity Bay, Newfoundland. Modified from MacDonald and Thompson (1986a).

8.4.3 Reproductive Effort

The growth and fecundity of any organism are clearly influenced by the quality of the environment, and pectinids are no exception. One question which has preoccupied life-history theorists has been the effect of environmental variation on fitness characteristics such as reproductive effort within single species. Much of the experimental and ecological work on the reproductive energetics of bivalves and other aquatic invertebrates has been stimulated by the need to test empirically some of the predictions of demographic theory, although these studies have also provided useful insights into the ecology of several species, particularly in determining the degree of intraspecific variation in growth and reproductive output. Such research on pectinids has often focussed on water depth as an environmental variable (MacDonald et al. 1987; Barber et al. 1988), although there are studies in which inshore and offshore populations have been compared (MacDonald and Bourne 1987) or scallops in suspended culture compared with those growing on the bottom (MacDonald 1986). In all cases variation between populations is attributable not to factors such as depth *per se*, but to differences in food, temperature, salinity or other characteristics which define a particular water mass. In *Patinopecten caurinus*, for example, MacDonald and Bourne (1987) found that somatic production, gonad output and reproductive effort were all greater in animals from the productive inshore waters of the Georgia Strait, British Columbia, than in those from the cool, deeper water below the euphotic zone off the west coast of Vancouver Island (Fig. 8.5).

The most comprehensive information on intraspecific variation in energy partitioning by a pectinid has been obtained for the giant scallop *Placopecten magellanicus*, which occurs in the northwest Atlantic. MacDonald and Thompson (1985b) studied several populations of this species distributed along depth gradients in shallow inlets on the southeast coast of Newfoundland and in Passamaquoddy Bay, near St. Andrews, New Brunswick. For two of the Newfoundland locations, Sunnyside and Colinet, temperature and food availability (energy content of the seston) were measured throughout the year at selected depths from which scallops were sampled, whereas for other sites only temperature data were obtained (MacDonald and Thompson 1985a). At all locations except St. Andrews, the number of annual day degrees was a decreasing function of depth. Annual food availability was negatively correlated with water depth at Sunnyside in 1982, but not in the subsequent year, whereas at Colinet no variation in food ration was observed between depths in 1982 or 1983. These differences in environmental conditions at various depths were reflected in the values obtained for somatic production (Pg) and reproductive output (Pr) by individual scallops, because at all locations except Colinet and St. Andrews there was a negative correlation between age-specific Pg and depth, and in general Pr at any given age was also greater in scallops from shallower water. Thus for at least one site (Sunnyside) a direct relationship was demonstrated between favourable environmental conditions and enhanced Pg and Pr (especially the latter), and in other (Colinet) no differences were observed in age-specific Pg and Pr between scallops from various depths, owing to the absence of a depth gradient in food availability at this location. Age-related reproductive effort, whether expressed as $Pr/(Pg + Pr)$ or as Pr per unit ingested ration, was also greater in scallops from shallow water at Sunnyside, but

there was no such variation at Colinet. The lack of a correlation between Pr or Pg and depth at St. Andrews was attributed to unusual hydrographic conditions in the Bay of Fundy, where there is extreme vertical mixing as a result of tidal forces. Reduced fecundity has also been observed in a population of *P. magellanicus* from deep water in the Gulf of Maine (Barber et al. 1988), and Skreslet and Brun (1969) recorded a higher gonadosomatic index in Iceland scallops *Chlamys islandica* from shallow water than those from greater depths.

In addition to variation in Pg, Pr and reproductive effort between conspecifics from different depths or localities, comparisons of observations made in different years on one or more populations provide further evidence of intraspecific variation. Shafee and Lucas (1982) found much greater differences in Pr than in Pg or Ps between consecutive years in *Chlamys varia*, resulting in large interannual variation in reproductive effort (Fig. 8.6). In several populations of *Placopecten magellanicus*, MacDonald and Thompson (1985b) and MacDonald et al. (1987) also recorded small differences in Pg between years, but greater variation in Pr and reproductive effort (Fig. 8.7), especially in shallow water. There was a good correlation between reproductive output and food availability for scallops from shallow water in each of the two years for which data were obtained at Sunnyside, although in deeper water this trend was not observed. Annual variation in total production of individual scallops was largely a function of variability in gamete output. These results are consistent with life-history theory, which predicts that reproductive effort should increase when conditions are favourable (Goodman 1979). MacDonald and Thompson (1985b) suggested that the investment of surplus energy in gamete production at favourable locations or in good years may be an appropriate strategy for a species like *P. magellanicus* which experiences a variable, unpredictable environment. The highly variable recruitment which is characteristic of *P. magellanicus* in Newfoundland, and perhaps elsewhere, may be a consequence of a conservative strategy of controlled growth and opportunistic reproduction.

In a study of growth and reproduction in populations of the giant scallop *Placopecten magellanicus* from southeast Newfoundland to northern New Jersey, MacDonald and Thompson (1988) found considerable intraspecific variation in the production of somatic and germinal tissue, but only in Pr was there any evidence of latitudinal differentiation, both Pr and reproductive effort (Fig. 8.7) being greater in New Jersey scallops than in those from more northerly locations. This enhanced reproductive output was associated with reduced longevity, which is consistent with theory discussed by Calow (1979). Variation on a microgeographic scale, such as that observed between depths at Sunnyside and other locations in Newfoundland, may exceed variation on a latitudinal scale, owing to the sensitivity of the animal to local environmental conditions. A considerable body of evidence has accumulated which demonstrates great phenotypic plasticity in the reproductive output of scallops and other bivalves over small geographic ranges (Bayne et al. 1983; Bricelj et al. 1987a; MacDonald and Bourne 1987; MacDonald and Thompson 1988). The resulting variability in reproductive effort is illustrated in Fig. 8.7, which presents only some of the available data for *P. magellanicus* but includes the maximum and minimum values recorded, i.e., covers the entire range for the species. Although there is little information on the degree to which variation in growth and reproduction is

genetically controlled, there is clearly a strong environmental influence. Thus in the Newfoundland populations of *P. magellanicus* studied by MacDonald and Thompson (1985a; b) not only were large variations in reproductive output observed along depth gradients over horizontal distances of approximately 100 m, which makes genetic differentiation extremely unlikely, but the values for Pr were also correlated with food availability. There is a large environmental component in the determination of somatic growth, fecundity and reproductive effort in bivalves which operates in the short-term and allows opportunistic exploitation of a variable food resource, but there must also be a genetic component which is less well documented and more difficult to quantify, and which presumable provides a mechanism for adaptation to long-term changes in the environment.

8.5 REPRODUCTIVE VALUE AND COST

8.5.1 Residual Reproductive Value

The concept of reproductive value was introduced by Fisher (1930) as a measure of the average production of young expected from a female over her lifetime. This was modified by Williams (1966), who considered reproductive value in terms of two components, current fecundity and future reproductive potential or residual reproductive value (RRV):

$$RRV = \sum_{t=x+1}^{\omega} \frac{l_t}{l_x} m_t \quad (2)$$

Where l_t/l_x is the probability of survival from age x to age t , ω is the age of last reproduction and m_t is gamete production at age t . This index appeals to life-history theorists because it incorporates two characteristics, fecundity and mortality, which are likely to be under selective pressure. Thus RRV is probably a better fitness correlate than reproductive effort, but from the point of view of the empiricist it is less attractive because it requires an estimate of mortality for each age class. In many bivalve species this is difficult and tedious, with the result that there are few treatments of RRV in the literature. A uniform mortality rate has often been assumed for all age classes, but this is a questionable practice, since in some populations of at least two species, *Mytilus edulis* and *Placopecten magellanicus*, mortality is greater in very young and very old individuals than in those of intermediate age (Thompson 1984b; MacDonald and Thompson 1986b).

Vahl (1981b) demonstrated that in *Chlamys islandica* RRV is low in young individuals, but increases as they grow older, reaching a poorly-defined maximum at about 13 years before falling to zero at 23 years. In the mussel *Mytilus edulis* maximum RRV occurs at 4–6 years (Bayne et al. 1983; Thompson 1984b), and there are differences between populations in age related RRV which correlate well with environmental quality (Bayne et al. 1983). According to MacDonald et al. (1987), RRV in *Placopecten magellanicus* from various depths at Sunnyside and Colinet, Newfoundland, attains maximum values at 4–5 years (Fig. 8.12). These authors also found differences in the magnitude of RRV which, like reproductive effort, was greater in scallop from shallow

Figure 8.12. Age-related residual reproductive value in the giant scallop *Placopecten magellanicus* from 10 m and 31 m depth at Sunnyside, Trinity Bay, Newfoundland during consecutive years. Modified from MacDonald et al. (1987).

water at Sunnyside that in those collected from deeper water, and which also varied between years in the former group (Fig. 8.12). No consistent differences in RRV were observed between years or between depths at Colinet, where depth gradients in temperature or food availability were not apparent.

8.5.2 Reproductive Cost

Calow (1979) argued that an index of reproductive effort should take into account the degree to which reproduction represents a drain on the non-reproductive energy requirements of the animal. He proposed a physiological index of reproductive cost (C) expressed in terms of energy input I, reproductive output Pr and the metabolic demand R* of the somatic tissue:

$$C = 1 - [(I - Pr)/R^*] \quad (3)$$

The measurement of absorbed ration I over an entire reproductive cycle is difficult, and the separation of the measured metabolic rate into reproductive and non-reproductive

components in natural populations presents a further challenge. Consequently this index has not been used as extensively as others, and the only estimates of reproductive cost in bivalves are those which have been made by Bayne et al. (1983) and Thompson (1984b) for the blue mussel *Mytilus edulis*, and by MacDonald et al. (1987) for the giant scallop *Placopecten magellanicus*. In both species the cost of reproduction was low in small individuals, but increased as they grew, reaching maximum values in the largest, most fecund animals (Fig. 8.13). In the population of *P. magellanicus* studied by MacDonald et al. (1987) at Sunnyside, Newfoundland, reproductive cost was lower in scallops from deep water than in those from shallow water (Fig. 8.13), owing largely to reduced fecundity in the former group. In general, values for reproductive cost were negative, suggesting a “restrained” reproductive strategy (Calow 1979), whereas positive values, indicating a diversion of energy from somatic maintenance to gamete production (i.e., a “reckless” strategy), were observed only in large individuals from shallow water, where conditions were more favourable.

Figure 8.13. Age-related reproductive cost in the giant scallop *Placopecten magellanicus* from 10 m and 31 m depth at Sunnyside, Trinity Bay, Newfoundland. Modified from MacDonald et al. (1987).

8.6 POPULATION PRODUCTION

Energy flow in populations can be evaluated by expanding the concept of an energy budget for individuals to include parameters relevant to populations. Production (estimated as $P = \Delta B + E$) includes the change in biomass (ΔB) which results not only from the growth of individuals but also from the addition of new individuals through recruitment and immigration, and must consider energy losses or elimination (E) through mortality and emigration. In a stable population, biomass does not vary annually because energy gains through production are counterbalanced by mortality losses. Although expenditure on gametes is a major component of individual production, there is often a major loss to the population when the animals spawn. Because the partitioning of this production into somatic growth and gamete output is age dependent, estimates of population production not only require information on the number of individuals per unit area, but also their age structure, which is often described by an age-frequency distribution. Indices of population production or turnover ratios (P/B) depend upon the balance between young, fast-growing animals and older, slow-growing, fecund individuals.

One means of estimating population energy flow requires the integration of physiological measurements such as ingestion and metabolic rates made under natural conditions with population characteristics such as density, growth rate and reproductive output. The limitations of extrapolating short-term laboratory studies of individual animals to whole populations under field conditions have been discussed by Bayne and Newell (1983) and some investigators have gone to considerable lengths to measure physiological activity under as realistic conditions as possible, especially in the field (Bayne et al. 1977). The classical procedure for the assessment of population energy flow, however, is to estimate production either from the increase in biomass per unit time, or by the application of "standard" P/B ratios to measured biomass. This is a direct approach, since production represents the net result of physiological activity in the organism, and it eliminates the need for physiological measurements and the extrapolation of data. The use of a P/B ratio is particularly attractive, because it provides an estimate of production from a single biomass measurement without the need for repeated sampling, but the difficulty here is that most bivalves undergo pronounced seasonal changes in body weight and energy content, so that the production estimate is sensitive to the time of sampling. One major problem with direct estimates of population production is that they often consider only the somatic growth component and omit reproductive output, which in many bivalves can result in an underestimate of total production by as much as tenfold, depending on the species and the age composition of the population (Bayne and Worrall 1980; Griffiths 1981b; Thompson 1984b). The magnitude of the underestimate will also depend on the stage of gonad development at the time of sampling. Wherever possible, sampling should be carried out immediately before and immediately after spawning, so that gamete production may be determined as well as somatic growth.

Despite the frequent use of energy units to express production per unit area, meaningful comparisons between populations remain difficult because methodology is often not uniform and there are spatial and temporal differences in population structure

which are seldom quantified (Griffiths 1981b; Broom 1983). Pectinid populations appear to be less productive than those of many other bivalves (Table 9 in Broom 1983). This is presumably the result of differences in population structure, especially the relatively low densities characteristic of many scallop species, or of behavioural patterns, particularly migration after settlement, rather than of any physiological properties of individual animals. For example, allocations of assimilated energy to respiration in the pectinids *Chlamys islandica*, *C. varia* and *Placopecten magellanicus* are similar to those of several other bivalves (Vahl 1981c; Shafee and Conan 1984; MacDonald and Thompson 1986a). For these three species, information is available on the relevant population characteristics, including physiological measurements and estimates of the various components of production (Vahl 1981a; c; Shafee and Conan 1984; MacDonald and Thompson 1986a; b). Despite some major differences in growth rate, maximum size, longevity and population density between these species, there are many similarities in their production and patterns of energy flow, e.g., as seen in the P/B ratios (Table 8.1). Although the metabolic demand represents a similar proportion of production in all three scallops, they differ greatly in the proportion which is lost through mortality (25–30% in *P. magellanicus*, 41% in *C. islandica*, and more than 100% in a population of *C. varia* which may be heavily fished). The lower values for *P. magellanicus* may be attributable to the predominance of older (larger) individuals, providing a size related refuge from predation similar to that described for the horse mussel *Modiolus modiolus* (Seed and Brown 1978).

Neither *C. islandica* nor *C. varia* grow as large as *P. magellanicus*, and may therefore be susceptible to predation throughout their life spans, as in the cockle *Cerastoderma edule* (Seed and Brown 1978). Between 15 and 25% of total production in *C. varia* and *C. islandica* is spent on gametes, compared with 46–72% in *P. magellanicus*, depending upon the population studied. The reproductive output of a 19-year-old giant scallop (approximately 170 mm in height) is equivalent to the combined output of 14 Iceland scallops of this age.

The significance of age structure and environmental conditions becomes apparent when intraspecific comparisons are made between populations from different locations. MacDonald and Thompson (1986b) found that the proportion of large individuals of *Placopecten magellanicus* was greater at Sunnyside, Newfoundland, than at Colinet, where the younger age classes predominated. As a result the Sunnyside population, with its high reproductive potential, spent almost three times more energy on gametes than on somatic tissue. *P. magellanicus* from Colinet is similar to populations of the hard clam *Mercenaria mercenaria* (Hibbert 1977) and the oyster *Ostrea edulis* (Rodhouse 1978) which also partition their production almost equally between growth and reproduction, although there is very little information available on intraspecific variation in population production for other bivalve species. The rapid growth and high fecundity of individual scallops from shallow water at Sunnyside has been attributed to favourable food and temperature conditions (MacDonald and Thompson 1985a,b), but the Colinet population was almost twice as productive as the Sunnyside one, owing to the greater density of the former. Some of the physical and biological factors that determine production operate at the level of the individual animal (e.g., the effects of food and temperature on scope for growth), others at the population level (e.g., the influence of substrate and ocean currents

Table 8.1

Chapter 9

Nutrition in Pectinids

Ana Farías and Iker Uriarte

9.1 INTRODUCTION

Over the last decade, the area of nutrition in larviculture of bivalve molluscs has undergone a period of great development, primarily due to increased implementation of controlled cultures under hatchery conditions. These operations extend from broodstock conditioning through production of small juveniles, with a larval culture phase of as long as four weeks between spawning and metamorphosis. One of the greatest costs involved in these types of culture is that of the food required, principally based on microalgae (Coutteau and Sorgeloos 1992; Uriarte et al. 2001). Much research has thus been centred on more efficient and cost-effective means for obtaining foods for each stage of the culture process, both in microalgal culture technology and in formulation of microalgal substitutes. This area has promoted the development of nutritional studies in bivalve molluscs for broodstock conditioning and larval culture, as well as for postlarval culture after metamorphosis until the progeny reach 2 to 10 mm in size.

9.2 PECTINID FEEDING

The pectinids are sestotrophic bivalve filter-feeders, which are capable of ingesting living and inert particles suspended in the water column (Lucas 1982). It has been observed that in bottom dwelling pectinids, inert organic material in the seston may be responsible for most of the energetic input (Hunauld et al. 2002), while it has been shown in other species that detritus may contribute to the diet during periods in which the environmental offering of phytoplankton is unable to satisfy their energetic requirements (Cranford and Grant 1990). Organic materials from discarded feed and faeces from salmon culture contribute to the diet of pectinids maintained in culture in southern Chile (42°S; Seguel et al. 1998). Phytoplankton is, however, the main nutrient source for pectinids as the nutritional value of organic detritus becomes degraded by bacterial decomposition, and leakage of its contained micronutrients.

Use of microalgae cultured in support of intensive bivalve culture, including pectinids, has promoted active monitoring of the nutritive characteristics of these algae in order to satisfy the nutritional requirements of broodstock, larvae and postlarvae. Of the traditionally used microalgal species in controlled bivalve culture, two species stand out, *Isochrysis* aff. *galbana* (clone *T-Iso*) and *Chaetoceros neogracile* (Coutteau and Sorgeloos 1992).

Based on the premise that utilisation of protein in food was most efficient when the protein contained essential amino acids in a ratio compatible with tissue formation, Webb and Chu (1983) proposed that the low nutritional value of some microalgae such as *Phaedactylum tricornutum* was due to an inadequate amino acid profile, as this alga lacked tryptophan. Microalgae currently considered to be of high nutritional value have similar essential amino acid profiles as the larvae in culture (Brown 1991), and contain higher concentrations of these amino acids than do the larvae. From this it is concluded that the protein in favourable microalgal diets presently used in molluscan hatcheries is of adequate quality, and that continued research on this protein should be directed to the area of its proportional quantity in culture diets.

Relevant to lipids, the pioneering work of Chu and Webb (1984) demonstrated the importance of essential fatty acids and the relation between n-3 and n-6 fatty acids, which promote growth in bivalves, and thus act as a quality indicator for microalgae. The survey mentioned above (Coutteau and Sorgeloos 1992) indicated that the preference for *T-Iso* and *C. neogracile* was associated with their high levels of total lipids and content of docosahexanoic acid (DHA) in *T-Iso*, and elevated levels of carbohydrates, eicosapentanoic acid (EPA) and riboflavin in *C. neogracile*. In general, varied diets favour controlled molluscan culture, with use of a DHA-enriched alga, such as *T-Iso* or other prasinophyceae, and an alga high in EPA such as *Chaetoceros* or other diatoms (Table 9.1).

Cultures of microalgae may be manipulated in order to increase their content of proteins, lipids, and carbohydrates, as well as increasing their levels of n-3 HUFA. Increases in algal biomass need to be achieved in order to make such microalgal production methods cost-effective. For example, methodology for increasing the protein content of microalgae involves increasing the nitrogen content of the algal culture medium, achieving a 50% rise above the normal cellular protein content (Fig. 9.1) and produces a significant increase in the growth rate of the microalgal culture.

In general, the majority of algal species used in molluscan cultures contain high levels of vitamins. The vitamin C found in the majority of microalgae fulfils the requirements of pectinids and other bivalves as the average values for this compound in these microalgae is between 0.11 and 1.62% of their dry weight and it is known that in fishes and crustaceans these requirements may be as high as 0.02% of the diet. Brown and Miller (1992) suggested the vitamin C found in the microalgae is efficiently incorporated into filter feeders. As with vitamin C, little is known concerning the riboflavin requirements of molluscs, although fishes and crustaceans may have requirements as high as $6 \mu\text{g g}^{-1}$ of the diet, and the microalgae used in molluscan cultures contain amounts of this vitamin generally greater than $20 \mu\text{g g}^{-1}$. *Chaetoceros gracilis* is one of the species with the highest content of this vitamin (Brown and Farmer 1994).

Adult pectinids often contain large numbers of their own eggs in their digestive tracts during the reproductive season, as well as particles of up to $950 \mu\text{m}$ (Shumway et al. 1987; Bricelj and Shumway 1991). They normally carry out negative selection of particles over $100 \mu\text{m}$ and have a high efficiency for retention of particles of less than $40 \mu\text{m}$ (Vernet 1977). Pectinid larvae efficiently retain particles from 0.5 to $8 \mu\text{m}$ depending on the size of the larva. The rate of consumption of food particles depends on a number

Table 9.1

Microalgal diets used in the feeding of Latin American pectinids. Data are listed in the same units as used in the references. (After Farías 2001).

Figure 9.1. Protein content of different mass cultures of a microalgal mixture consisting of *I. aff. galbana* (*T-Iso*) and *Chaetoceros neogracile* conditioned in media with high (IH + GH) and normal (I + G) nitrogen concentrations, or with *T-Iso* alone, conditioned in a high nitrogen concentration (IH). Each value is the mean of seven replicates. Bar = 1 SE.

of variables, including temperature, food concentration, nutritive value of the food, and water flow (Wildish et al. 1987; Bricej and Shumway 1991). Absorption both in larvae and in juveniles and adults is controlled by the levels of digestive enzymes in their digestive tracts (Samain et al. 1992). Digestion in pectinids occurs partially in the stomach and crystalline style sac, and partially within the digestive diverticula in the digestive gland. Since there are no salivary glands in filter feeding bivalves, the carbohydrases important in digestion occur in the digestive gland and crystalline style. Amylase has been detected in the stomach in a selection area composed of B type cells containing large granules (Benlimame et al. 1993). Amylase and laminarinase activity have been detected in the crystalline style, and act extracellularly at an acid pH in the crystalline style sac and stomach. The digestive gland is rich in intracellular carbohydrases such as glucosidases, galactosidases, and chitobiases, and intracellular peptidases have been detected, which may characterise them as “lysosomal” (Wojtowickz 1972; Boucaud-Camou et al. 1993). High extracellular amylase activity has also been detected in channels within the digestive gland without proteolytic activity. Aside from the absorption of macronutrients, larvae, juveniles and adults have mechanisms for the absorption of micronutrients, which is an energy-requiring process. These processes may

be saturable as a function of dose, such as in the case in the absorption of vitamin C in larvae of *Pecten maximus* (Seguineau et al. 1993).

Pectinids may be fed using different microalgal cultures under experimental conditions or in intensive culture. Most feeding and nutritional studies have been carried out with these types of diet, and although positive empirical results have been obtained, there has been little explanation of how natural diets fulfil the nutritional needs of these bivalves. Also, little is known concerning how the pectinids respond to the complex mixtures of bacteria, phytoplankton, and chemical signals, which affect them in their natural environment. Variability in nutritional quality of seston may range from 5 to 80% in organic content, with a C:N ratio from <4 to >26 (Bayne and Hawkins 1990). This spectrum may vary with the length of day, season of the year, or geographic locality, which make it difficult to define a "typical natural diet", or reasonably define the "normal" feeding behaviour of a bivalve. In *Placopecten magellanicus* a chemoreceptive mechanism has been described which operates at low concentration levels which allows the species to discriminate between types of particles prior to their capture and ingestion (Ward et al. 1992).

Given the high variability inherent in living cultures of microalgae, much research has been carried out on identifying potential microalgal substitutes. Pure-cultured microalgae is now available as a frozen paste, or in dried form, as are heterotrophic cultures of microalgae. These products may be used as supplements or even substitutes for traditional microalgal cultures. Yeasts have been tested with some success in clam cultures, but these have not been found useful for the pectinids due to their low nutritional value and their high rates of sedimentation. Tests made by substituting 50% of the traditional microalgal diet of juvenile *A. circularis* (Fundación CENAIM-ESPOL 1998) with yeast or dry microalgal powder produced a significant decrease in their growth in both cases when compared with normally fed controls. In tests where diets containing 100% yeast or dry microalgae were given to *A. circularis* juveniles, they failed to grow at all and almost all the individuals died by the fourth week of the experiment (Table 9.2).

Some thought was given in the past to the possibility of producing a well balanced diet for filter feeders by means of microencapsulation technology. These methods have still not emerged from the experimental stage; however, they are potentially useful for the study of nutritional requirements in bivalves in general (Kreeger and Langdon 1993; Seguineau et al. 1993).

Development of lipid emulsions for the feeding of bivalves has given good results at the experimental level. Coutteau et al. (1996a) and Caers et al. (1999) have shown that both pectinid juveniles and broodstock were capable of incorporating portions of the fatty acids present in lipid emulsions into their triglycerides. Lipid emulsions given as a 50% (w/w) supplement in the microalgal diet of *A. purpuratus* broodstock significantly increased lipid levels in their eggs (Caers et al. 1999). In mixed diets of 70% microalgae and 30% lipid emulsions, the broodstock of *A. purpuratus* reached better conditioning than those with a 100% microalgal diet (Martínez et al. 2000a). In diets for larval *A. purpuratus*, lipid emulsions may be substituted at up to 40% of the microalgal diet without affecting their growth and survival when compared with a diet of *I. galbana* (T-Iso) and *C. neogracile* (Uriarte et al. 2003). The microalgal diet for *A. purpuratus*

Table 9.2

Use of artificial diets in feeding *A. circularis*. The microalgal mixture was composed of *T-Iso* and *C. neogracile*. Results after four weeks of experimentation. Each value represents the mean and standard deviation of three replicates. (After CENAIM-ESPOL Foundation 1998).

Treatment	Increase in wet weight (mg)	Increase in dry weight (mg)	Increase in length (mm)	Survival (%)
100% algae	0.79 ± 0.06^a	0.4 ± 0.03^a	6.3 ± 0.4^a	98.3 ± 1.4^a
50% algae + 50% yeast	0.4 ± 0.05^b	0.2 ± 2.02^b	3.9 ± 0.45^b	95.0 ± 4.3^a
100% yeast	0.05 ± 0.07^c	-0.01 ± 0.05^c	0.2 ± 1.7^c	8.3 ± 10.1^b
50% algae + 50% dry algae	0.38 ± 0.05^b	0.19 ± 0.02^b	3.8 ± 0.2^b	95.8 ± 5.2^a
50% dry algae	0.01 ± 0^c	0.02 ± 0^c	0.1 ± 0.7^c	2.5 ± 4.3^b
Control (not fed)	-----	-----	-----	0 ± 0^b

Values with the same exponent within each column not significantly different ($P > 0.05$).

Figure 9.2. Experiment in 20-L tanks with *Argopecten purpuratus* larvae grown at 12°C and 19°C with three different diets: (A) = microalgae alone; (A + G) = microalgae plus 20% glucose; (A + S) = microalgae plus 20 starch. Each value is the mean of three replicates. Bar = 1 SE. (After Uriarte 2000).

juveniles may be substituted up to 20% with lipid emulsions enriched with EPA and DHA, but at a substitution level of 40% growth decreases (Fig. 9.2). At present there is at least one commercial mollusc hatchery which has incorporated routine use of lipid emulsions into its culture procedure (Sorgeloos 1998), and appears to be a useful alternative for replacing a portion of the microalgal diet in pectinids (Uriarte et al. 2003).

Use or not of substitutes for microalgae is highly dependent on the quality of the microalgae utilised in the culture procedure. Prior to the consideration of such substitutes, the high variability in nutritional value of cultured microalgae needs to be eliminated by standardisation of mineral nutrients (fertilisers), lighting conditions, photoperiod, temperature, and stage of harvest of the cultures. The concept of adding microalgal substitutes is only valid when there is a widely accepted "standard microalgal diet", a known portion of which can then be experimentally replaced by food supplements.

9.3 NUTRITIONAL REQUIREMENTS DURING REPRODUCTIVE CONDITIONING

The composition of diets administered to molluscan broodstock has been discussed as having a major influence on their reproductive capacity and on the quality of their gametes, (Robinson 1992a; Samain et al. 1992). Protein increase in the microalgal diet decreases the time to maturity, increases the fecundity of the females, and improves the energy balance in pectinid broodstock (Fariás and Uriarte 2001). Results of physiological analyses have shown that diets low in protein produce malnutrition in *A. purpuratus* broodstock characterised by a high degree of excretion of endogenous proteins to make up for lack of dietary proteins during reproductive conditioning. High respiratory rates are also observed under these conditions, probably due to an elevated level of carbohydrates in protein-deficient diets (Fariás and Uriarte 2001). Villalaz (1994a) suggest that the adductor muscle stores protein in support of reproductive activity on the gonad of *A. ventricosus*, reiterating the importance of proteins in the broodstock diet. A significant difference was observed between broodstock conditioned in a hatchery and broodstock conditioned at sea (Martínez et al. 1992) suggesting that microalgal diets produced in the hatchery are deficient in proteins, and therefore need to be enriched.

One of the nutritional factors that most affects the quality of spawnings in molluscs is the content of EPA in eggs, which is also the most abundant in larvae during metamorphosis (Robinson 1992b). The EPA/DHA ratio varies between species, which have been conditioned in the field and those conditioned in the hatchery (Utting and Millican 1997). The pattern of fatty acids in the lipids of the eggs reflects the lipids in the diet, where in *Chlamys tehuelcha* a strong correlation was observed between the fatty acid composition of the dominant phytoplankton and the lipid composition of the gonads (Pollero et al. 1979). Lipids in the eggs of marine molluscs are rich in n-3 HUFA, the origin of which is probably from diatoms and dinoflagellates (Pollero et al. 1979; Trider and Castell 1980; Napolitano et al. 1992; Robinson 1992b). This observation implies that developing embryos and emerging larvae have high n-3 HUFA requirements, which need to be derived from the diet of the broodstock. Martínez et al. (2000b) demonstrated that a 30% substitution of emulsions enriched with n-3 HUFA into the microalgal diet during

reproductive conditioning of *A. purpuratus* broodstock produced higher fecundity and better responses to spawning induction. Supplementing the broodstock diet with n-3 HUFA induced effects in the fatty acid profiles of the triglycerides in the eggs, but did not produce variation in the composition of their phospholipids (Caers et al. 1999). In comparing high-protein microalgal diets with diets normal in protein but 30% substituted with a lipid emulsion enriched with n-3 HUFA, *A. purpuratus* broodstock produced significantly better quality progeny on the high protein diet (Hernández 2001; Uriarte et al. 2004).

No requirements for carbohydrates have been demonstrated during the reproductive conditioning of pectinids, although accumulation of glycogen reserves has been observed in the muscle for subsequent use in gonadal maturation. Increase in the feeding ration has been shown to produce increases in carbohydrates in the gonad (Martínez et al. 2000b). In cultures of *A. purpuratus* grown in polyculture systems with salmon in Chile's Xth Region (42°S) accumulations of carbohydrate occurred in both muscle and gonad during observations made both in tanks and in the sea. This accumulation of carbohydrates arose from the availability of protein-lipid particles coming from artificial feeding of cultured salmonids, and produced a reproductive event in the pectinids in winter, which was not observed in control cultures of *A. purpuratus* distant from the salmon cultures (Seguel et al. 1998).

In addition to provitamin A activities, carotenoids are required for gonadal development and maturation, fertilisation, eclosion, and larval viability, as well as for other functions. Since these pigments originate in the phytoplankton, it is expected that filter feeders such as the pectinids might not be limited with regard to these pigments when fed on microalgal diets. Carotenoids observed in the gonad of *A. circularis* have included lutein and astaxanthin at a level of 2×10^5 mg g gonad⁻¹ (Escarria et al. 1989).

9.4 NUTRITIONAL REQUIREMENTS OF THE LARVAE

Larvae of *A. ventricosus* demonstrated better growth in a mixture of *I. galbana* and *C. gracilis* than when cultured separately with each of these algae; using the mixture, values for the daily deposition of protein were increased, as well as the apparent use of protein (Millán 1997). The factorial effects of the protein levels using microalgal and lipid-substituted diets on growth and survival, and energetic reserves in larvae have been compared for *A. purpuratus* (Machulas 2000; Uriarte 2000; Nuñez 2002). In all cases the best growth of the larvae was obtained using high-protein diets, while there were no detectable effects attributable to the lipid-substituted diet. Larval survival appeared to be independent of both protein and lipid dietary levels. Metabolism of energetic reserves observed in pectinid larvae fed with different levels of protein and n-3 HUFA (Uriarte 2000) showed that the protein content of the larvae did not vary due to type of diet, although the opposite was true for the lipids and the carbohydrates. Lipid levels in larvae increased in proportion to increase in lipid levels in the microalgal diet ($F_{\text{lipids}} = 6.09$, $df = 1,6$, $P = 0.05$) and the carbohydrates in the larvae were affected by the protein level in the diet, but not when protein was replaced by lipids in the diet ($F_{\text{protein}} = 9.93$, $df = 1,4$, $P = 0.03$). These results indicate a greater requirement for proteins during the larval

phase, which could be satisfied with a high protein microalgal diet. Microalgal growth in a high-nitrogen medium probably not only increases in protein content, but also may improve in availability of essential amino acids which could be limiting at lower protein concentrations.

There is considerable information available on the lipid requirements of larvae of marine organisms, primarily the fishes. These studies have centred primarily on the optimum requirements for highly unsaturated fatty acids (n-3 and n-6 HUFA) in early fish developmental stages. HUFA identified as essential for marine organisms include docosahexanoic acid (DHA), 22: 6n-3, eicosapentanoic acid (EPA), 20:5n-3, and arachidonic acid (ARA), 20:4n-6. These lipids are normally produced by phytoplankton and reach the larvae via the food chain. Only a portion of the fatty acids required in the diet serve in functions requiring esterified essential fatty acids in membrane phospholipids. The majority serves an energetic functions, such as a portion of the triglycerides. The remaining portions of the non-essential fatty acids are the saturated, monounsaturated, and remaining polyunsaturates (PUFA). Less than a decade ago, it was thought that only crustaceans had requirements for phospholipids in their diets, and that these could be biosynthesised by fishes. However, the use of artificial diets has shown that larvae of marine fish have a limited capacity for the biosynthesis of phospholipids. Phospholipids are required in aquatic feeds to form the chylomicrons in order to transport triglycerides across the intestinal mucosa to the lymph and low-density lipoproteins (Sargent et al. 1999b). Phospholipid requirements have not been determined for molluscs; most studies have indicated a requirement for fatty acids. Sargent et al. (1999a) proposed that the ideal lipid composition in the diet of marine larvae would be one which duplicated the lipid composition of the vitellum in the eggs based on its content of phospholipids and triglycerides, where the phospholipids are naturally rich in HUFA. This suggests that larvae would be saved the task of biosynthesis of phospholipids and PUFAs, and the triglyceride content would provide the energy sufficient for larval development. Experimental diets might be useful for definition of optimal levels of lipids consistent with those hypothesised over the last three years (Geurden et al. 1997, Fontagne et al. 1998), but technological developments so far do not allow preparation of a diet of this type (Sargent and Tacon 1999).

During molluscan larval development a greater percentage of n-3 HUFA are observed in the phospholipid fraction than in that of the triglycerides due to a greater selective insertion of n-3 than n-6 in the membrane phospholipids (Chu and Webb 1984). Larvae of *P. maximus* show a restricted capacity for desaturation of fatty acids, although this capacity is sufficient for regulation and stabilisation of the PUFA content of the membrane phospholipids (Soundant et al. 1998). The n-3 HUFA composition of phosphatidylcholine in larvae of *A. purpuratus* varies in relation to the diet administered, while the composition of the phosphatidylethanolamine is highly conservative and is maintained independent of the diet (Farias et al. 2001).

Early studies of larval bivalve molluscs demonstrated that their triglycerides were independent of the diet, while phospholipids were highly conservative and tended to be independent of the composition from that of the microalgae used as food (Waldock and Nascimento 1979, Napolitano et al. 1988). Studies using lipid emulsions enriched in n-3

HUFA as supplements to the microalgae, however, have shown that the composition of the polyunsaturated fatty acids in the diet affected both the larval triglycerides and their phospholipids, and that their EPA/DHA became the same as that of the emulsions offered (Coutteau et al. 1996a). It has also been found that the PUFA in *P. maximus* in the phospholipids are highly deficient in EPA, DHA, or ARA (Soudant et al. 1998), and results of studies of premetamorphic larvae have shown that the microalgal diets considered to be of high nutritive value can be further improved by adding n-3 HUFA emulsions. These provide better growth and survival in the early postlarval stages (Coutteau et al. 1994). Marty et al. (1992) found that larvae of *P. maximus* had high dietary requirements for DHA, while Delaunay et al. (1993) detected a requirement for EPA and ARA in larvae of this species. Coutteau et al. (1996b) showed that larvae of *Placopecten magellanicus*, although able to efficiently incorporate n-3 HUFA from lipid emulsions, did not demonstrate improved growth or survival during the larval period, which may be because the microalgal diet satisfied their requirements for EPA and DHA. Uriarte et al. (2003) have shown that at 19°C, using diets of *T-Iso* and *C. neogracile*, larvae of *A. purpuratus* did not require n-3 HUFA lipid supplementation. They also showed that the microalgal diets of *A. purpuratus* larvae can be 40% substituted with lipid emulsions without affecting larval growth and survival. This may be because the PUFA stored in the neutral lipids of the larvae are utilised during metamorphosis for supplying energy, and perhaps as well for synthesising new membrane phospholipids (Delaunay et al. 1993). The studies of Thompson et al. (1993, 1994) have shown that in at least *C. gigas* and *Patinopecten yessoensis* the increase of dietary EPA and DHA was not beneficial. These authors suggested that the best diets for bivalve larvae were those high in saturated lipids, which only contained moderate quantities of polyunsaturated lipids, because the energy from the food was more efficiently utilised when it is liberated via β oxidation of saturated fatty acids. The studies of Sargent et al. (1999b) point rather to threshold concentrations of PUFA dependent on the interrelations with the essential n-3 HUFA. Larvae of *A. purpuratus* show better growth and survival with raised amounts of DHA/EPA in the diet, together with low values for EPA/HUFA, suggesting that the dietary EPA is less important, probably because the larvae may obtain it by desaturation of 18:3n-3 (Farías et al. 2001). Also in *A. purpuratus* larvae, the levels of ARA remain relatively constant even when they are fed diets not containing this fatty acid (Farías et al. 2001), thus suggesting it is not a dietary requirement for development of these larvae. An elevated content of EPA was observed in D-larvae of laboratory reared *A. purpuratus* fed with a mixture of *Nannochloropsis oculata* + *T-Iso* + *C. gracilis* at a 1:1:1 cell dry wt. ratio (Martínez 1991), which became reduced by up to 27% in pediveliger larvae at 16 days. Concurrently, the levels of DHA and ARA showed stable values throughout the entire larval development. The EPA/DHA ratio declined from 1.5 to 0.5 and the DHA/ARA ratio remained at about 12 during the entire period (Table 9.3). These results may indicate a use of the EPA in energy metabolism while the DHA tended to be conserved and maintained at high levels during the entire larval period. Farías et al. (2003) suggested that *A. purpuratus* larvae may be capable of selectively retaining DHA or converting sufficient 18:3n-3 and 20:5n-3 to 22:6n-3 for fulfilling their requirements.

Table 9.3

Nevejan et al. (2002) observed a high level of survival and development to the premetamorphic phase in larvae fed with *Dunaliella tertiolecta* supplemented with coconut oil. This microalga is deficient in HUFA, which provides additional evidence that pectinid larvae have a high capacity for the desaturation of linolenic and linoleic fatty acids. These studies did not, however, control for the possibility that bacterial flora of the culture tanks or in the digestive tracts of the larvae might be active in the synthesis of n-3 HUFA, or detect if true *de novo* synthesis of these fatty acids was accomplished by the larvae.

Larval requirements for fatty acids may vary significantly with variations in culture temperature. There are currently debated results concerning the effects of diet, temperature and their interactions on larval fatty acids, phospholipids and triglycerides. Also controversial have been comparisons made between similar species with different geographical origins which have been cultivated in a common habitat (Beninger and Stephan 1985). Studies on eggs of *P. magellanicus* from two geographically separated

populations showed that eggs from broodstock originating at 31 m depth had a high content of DHA in their phospholipids while those from 10 m depth had significantly lower concentrations of this lipid. The lower temperature of the deeper waters compared with that of shallower waters during the last phases of gametogenesis may have caused the variation in the fatty acid profile of this species, discarding diet as the determining factor in this variation, given that the fatty acids in the triglycerides was similar in the scallops from both habitats (Napolitano et al. 1992).

On theoretical grounds, it can be supposed that lipids (rather than carbohydrates) would have evolved as the primary energy source in tiny larvae of molluscs such as those of bivalves, as they are not only a more concentrated energy source, but also aid in the floatability of these planktonic organisms. The carbohydrates assume importance during the benthic phase of bivalve existence, with feeding habits adapted to ingestion of carbohydrate-rich particulate food of plant origin. Within a month after metamorphosis, tissue carbohydrates become more abundant than lipids in *A. purpuratus* tissues (Farías et al. 1998). For this reason it is probable that in larvae the hemolymph glucose levels are maintained by gluconeogenesis, to be replaced by glucogenesis and glucogenolysis only after metamorphosis. The addition of carbohydrates as glucose and soluble starch to *A. purpuratus* larvae cultured with *T-Iso* and *C. gracilis* produced no increase in their growth, while their survival was negatively affected by the use of starch (Uriarte 2000; Fig. 9.2). So, carbohydrates are not important determining factors of quality in the diet of larval bivalves. Whyte et al. (1989), however, found that quantity of dietary carbohydrates significantly increased the nutritional condition of larvae of *Patinopecten yessoensis*, suggesting an important role for carbohydrates in conserving nutrients such as proteins and fatty acids for tissue synthesis rather than as energy sources.

Vitamin requirements in diets of marine species vary with the species in culture, growth rate, capacity for vitamin synthesis by symbiotic microorganisms in the digestive tract, and the composition of ingested food. For species such as the pectinids which feed on phytoplankton, it is unlikely that vitamin deficiencies occur since the microalgae, particularly in the exponential phase of growth, contain sufficiently high levels of vitamins to satisfy the known requirements of various marine species (Seguineau et al. 1993). Accumulations of vitamins C and E have been observed in *P. maximus* during larval development, accompanied by a large reduction in riboflavin (B₂); the latter vitamin was the least abundant among those studied by Seguineau et al. (1993).

The mineral requirements of larval pectinids are probably at trace levels except for calcium required for production of the shell. Since seawater contains appreciable levels of calcium and trace minerals, uptake of these substances from this medium undoubtedly relies on ingestion and active transport of needed minerals across membranes of marine animals (Tacon 1990).

9.5 POST-METAMORPHIC NUTRITIONAL REQUIREMENTS

Increase in growth rate from metamorphosis to the 2-mm size as a result of administration of high-protein diets has been observed in pectinids, where the growth period between settlement and transfer of "pre-seed" to sea was reduced from 50 to 35

days (Uriarte and Farias 1995). This was due, at least in part, to the fact that in postlarvae of *A. purpuratus* food absorption efficiencies may vary between 74.6% (± 2.7) for a high protein *T-Iso-C. gracilis* mixture to 30.8% for a mixture of the same microalgae cultured to have a low protein content. Intermediate values for absorption were observed using this mixture when the algae were cultivated in traditional medium (Uriarte and Farias 1995).

The above cited stimulative effect of the high protein diet could not be duplicated with "seed" scallops 6 mm in length, suggesting that there was a greater requirement for proteins in the diet at the postlarval stage than in more advanced stages of growth in these scallops (Uriarte and Farias 1999). Low-protein diets produce reduced growth which was only slightly superior to that observed when the postlarvae were held without food, and began to experience high mortality. Postlarvae maintained on low-protein microalgae show high respiratory rates, probably associated with the higher relative carbohydrate content of this diet. The significant decrease of protein in hatchery-produced juveniles of *A. purpuratus* compared to those maintained at sea as observed by Martínez et al. (1992) reiterates the importance of enrichment of proteins in the microalgae in controlled cultures.

Regarding lipids, the existence of mechanisms in juvenile bivalves have been proposed for the desaturation and elongation of fatty acids which allow them to synthesise EPA and DHA when these are unavailable from microalgae. Experiments with seed-sized *C. gigas*, *Ostrea edulis*, and *Venerupis pullastra* showed that their growth was less when they were fed microalgae deficient in n-3 HUFA than when they were fed with mixtures of microalgae which contained EPA and DHA, or when these lipids were added as dietary supplements (Langdon and Waldock 1981; Waldock and Holland 1984; Uriarte et al. 1990; Albentosa et al. 1994). This information has served as empirical evidence supporting the concept that fatty acids are necessary in the diets of juvenile molluscs. The importance of ARA as an essential fatty acid was demonstrated by Caers et al. (1998) working with juvenile *Tapes* sp. clams. She also indicated that the EPA/DHA and DHA/ARA ratios were those definitively affecting the degree of impact that supplementing these fatty acids could have on the growth of juvenile molluscs. Martínez et al. (1992) found that early juveniles of *A. purpuratus* had a higher content of DHA when they were cultured at sea than when cultured in the hatchery, suggesting that the hatchery diet used (*T-Iso*, *C. gracilis* and *C. calcitrans*) was deficient in this fatty acid.

In the culture of *Nodipecten subnodosus*, Velasco (1997) found that larvae fed with a mixture of *I. galbana* (*T-Iso*) and *C. calcitrans*, or with *T-Iso* alone, were able to develop to metamorphosis, while the same larval development could not be obtained with *C. calcitrans* alone. Although this author did not discuss the nutritional quality of the diets, it is probable that a deficiency of DHA in *C. calcitrans* was one of the principal factors responsible for this result. Postlarvae of *A. purpuratus* obtained in the laboratory by Martínez (1991) had a 25% lower content of EPA after metamorphosis of the larvae, while the levels of DHA and ARA remained high.

EPA and DHA are essential lipids in postlarvae and juvenile oysters, and deficiencies in these compounds provoke retardation in their growth (Chu and Webb 1984). Lipid emulsions enriched with EPA and DHA may efficiently replace up to 20% of a microalgal

diet for *A. purpuratus* although not producing a significant increase in their growth rate (Uriarte et al. 2003). Nuñez (2002) studied the joint effect of protein in the microalgae and substitution of a portion of the microalgae by lipid emulsions enriched with EPA and DHA using *A. purpuratus* seed of 4 mm in length. Growth of the seed was not affected by the protein levels in the microalgal diet, but it was affected by the degree of replacement of the lipids; i.e., when 40% of the microalgae were replaced by lipids, there was a negative effect on the growth of the juveniles, while no differences were noted at replacement levels from zero to 20% (Fig. 9.3). Survival of these postlarvae was neither affected by the protein levels or by replacement of the lipids.

Carbohydrates may improve the growth of juvenile bivalves when their levels are raised in a microalgal diet, and once adequate levels of proteins and essential fatty acids have been provided (Enright et al. 1986). Increase in dietary carbohydrates may be achieved by cultivation of microalgae deficient in nitrogen, and adding adequate fractions to mixtures containing microalgae, which contain high levels of protein. Carbohydrase-type enzymes have been found in juvenile and adult bivalves (Samain et al. 1992), and for juvenile *P. maximus* the carbohydrate digestive capacity can limit the growth, mainly in the groups of 4-mm scallops (Økland et al. 2001). The greater accumulation of carbohydrates in juvenile scallops cultured under hatchery conditions compared with congeners cultured at sea demonstrated that microalgal diets produced in the hatchery contained higher energetic levels than those available in the environment (Martínez et al. 1992).

Although there are no studies on the vitamin requirements of postlarval pectinids, in accord with Segueineau et al. (1993) microalgal diets are capable of supplying sufficient levels of vitamin C and other vitamins required by most of the marine species.

Figure 9.3. Growth rates of 4 mm *Argopecten purpuratus* seed fed with high protein (IH/GH) *T-Iso* + *C. neogracile* and normal protein (I/G) microalgae, and levels of substitution of microalgae by lipid emulsions EmDHA and EmEPA of 0, 20 and 40% of the dry weight of the microalgae. Each value is the mean of four replicates. Bar = 1 SE. (After Nuñez 2002).

9.6 SUMMARY

Fulfilment of the nutritional requirements of pectinids in the reproductive conditioning, larval culture, and postlarval culture phases is determined by the levels and quality of the proteins and lipids in the diets utilised in their culture. The protein content of the microalgal diet affects the time to reach maturity, the fecundity of the females, and the energy balance in the broodstock, showing that diets high in protein favour all these parameters and also improve the quality of the larvae. An increase in the protein content of microalgal food by manipulation of their culture medium significantly increases larval growth and also favours improved growth of the postlarval juveniles to the 5 mm size.

Pectinid larvae show greater growth and survival when the diets contain high levels of DHA/PA together with low values for EPA/HUFA, with EPA being less important because the larvae are efficient in desaturation beginning with the linolenic acid (18:3n-3), and also seem to have the capacity for obtaining ARA from linoleic acid (18:2n-6). The microalgal diet for pectinids in the larval phase may be substituted up to 40% by lipid emulsions enriched with EPA and DHA, while in the postlarval phase to 2 mm this substitution may be up to 20% of the microalgal diet without damaging growth and survival in this phase.

The carbohydrates begin to be important in late juvenile stages, which may be related to availability of enzymes in the digestive system where amylases only appear after the scallops reach the 5 mm size. Pectinids at all stages are assured of adequate levels of vitamins and pigments when fed with microalgae. Micronutrients in the marine environment of the scallops readily provide their mineral requirements by direct absorption from seawater.

Chapter 10

Genetics

Andy Beaumont

10.1 INTRODUCTION

Before protein electrophoresis was developed and applied to the study of population genetics (Harris 1966; Lewontin and Hubby 1966) little was known of the genetics of any scallop species, or indeed any other bivalve mollusc. Naturally, early use of protein electrophoresis to detect allozyme loci concentrated on those species such as humans and fruit flies about which much was already known, but as the methodology became more easily accessible and cheaper, allozyme polymorphisms were investigated in a wider range of species. A glance at the references for this chapter will illustrate that the earliest publications on scallop allozymes appeared some ten years after the method had been developed (Beaumont and Gruffydd 1975; Mathers 1975). Although chromosome genetics had been studied in many organisms much earlier than this, descriptions of chromosome numbers and karyotypes of scallops were also only appearing in the literature at around this time (Beaumont and Gruffydd 1974; Ieyama 1975).

In general, genetic studies in scallops have not been aimed at the furtherance of the science of genetics, but rather at the application of genetic methods to problems relating to the biology of the species. These problems include the phylogenetic relationships among species, the degree of gene flow among conspecific populations, the degree to which life history parameters or physiological and adaptational responses may be determined by genetic differences among individuals within populations. Of particular importance, also, is the increasing awareness of the relevance of genetics to the fishery and aquaculture of scallops.

Because this chapter appears in a volume intended as a general introduction to the biology and ecology of scallops and their potential for aquaculture, the assumption is made that not all readers will be familiar with the genetic methodology or terminology described. Therefore short explanations and discussions of relevant techniques and concepts are provided at appropriate points together with further references to the wider literature. For a general introduction to biotechnology and genetics in fisheries and aquaculture see Beaumont and Hoare (2003).

For the purpose of review the various studies of the genetics of scallop species could be classified in at least three different ways: according to the genetic approaches employed, according to species studies, or according to the question being addressed. The first approach has been adopted here and the chapter is divided into three main sections. The first covers chromosomes and ploidy manipulation, the second introduces genetic markers (both protein and DNA-based) and their use in population genetic and

systematics, and the final section deals with hybridisation, inbreeding and quantitative genetics. Because of the extent of the information available within the second section, a part of it is subdivided on a species by species basis.

10.2 CHROMOSOMAL GENETICS AND PLOIDY MANIPULATION

10.2.1 Chromosome Numbers and Karyotypes

The chromosomes are normally invisible in the cell nucleus but become visible during the process of cell division when they coil and contract and become associated with a microfibrillar structure, the spindle. The diploid ($2N$) number of chromosomes present in each somatic cell consists of a haploid (N) number of homologous pairs of chromosomes of identical size and shape except where sex chromosomes are present. During mitotic cell division each chromosome is replicated to form 2 chromatids which divide and separate into the daughter cells. During the production of gametes from the germ cells, however, two maturation divisions take place, meiosis I and meiosis II. The first is a reduction division in which each resultant nucleus receives one chromosome from each of the homologous pairs and is therefore haploid. The second maturation division, meiosis II, is effectively a mitotic division of the chromosomes into chromatids. The consequences of meiosis I and II are therefore the production, from one germ cell, of four haploid nuclei. In males, four spermatozoa are produced from each germ cell but in females unequal cytoplasmic division during meiosis I results in one haploid set of chromosomes remaining in the egg while the other set is extruded within the first polar body. Similarly, the second polar body contains one of the sets of chromosomes derived from meiosis II. The first polar body may occasionally undergo its own meiosis II giving three polar bodies.

In scallops, as in most other bivalves, which release their eggs directly into the sea, the chromosomes in the egg are initially uncontracted and contained within the nuclear membrane, the germinal vesicle. In laboratory spawnings, both *P. magellanicus* and *P. maximus* eggs are initially non-spherical but soon round off (Gruffydd and Beaumont 1970; Desilets et al. 1995). According to Desilets et al. (1995) the germinal vesicle has broken down by the time *P. magellanicus* eggs are released, but in *P. maximus* it is possible to identify the germinal vesicle in the non-spherical eggs on their release and the breakdown of the vesicle is coincident with the eggs becoming spherical. At some point, which may therefore vary between species, the germinal vesicle breaks down and the homologous pairs of chromosomes come to lie, as bivalents, on the metaphase plate of the meiosis I spindle (Metaphase I). Scallop eggs then remain at this stage until activated by sperm attachment. Desilets et al. (1995) report that *P. maximus* oocytes are fertilised at the germinal vesicle stage, but all our observations on *P. maximus* indicate that the germinal vesicle has almost always broken down before egg activation. Nevertheless, one of the difficulties in establishing the earliest possible timing of egg activation in laboratory trials is that eggs are usually kept separate from spermatozoa before mixing, or samples are not taken immediately on release. In the case of *P. maximus*, which is a hermaphrodite, a small proportion of eggs are usually found to be self-fertilised. In this

case, it is possible that spermatozoa attach to the egg during passage along the gonoduct, or immediately on release, and eggs at this point would still have an intact germinal vesicle.

Once activated by the attachment of spermatozoa, meiosis I and II are completed and the first and second polar bodies are extruded sequentially at the same position on the egg surface. In the laboratory, in 32‰ filtered seawater at 15°C, the first polar body is usually extruded from *P. maximus* eggs within 25 minutes and the second within 50 minutes from activation (Gruffydd and Beaumont 1970). The process seems to be a little slower in *Placopecten magellanicus*, with anaphase I at 30 minutes and anaphase II at 60 minutes after activation of the egg by spermatozoa (Desilets et al. 1995). However, the trials with *P. magellanicus*, although at the same temperature (15°C), were carried out in pH-adjusted seawater at 28‰ salinity and this may have affected the speed of development. Lower temperatures clearly slow the process because, in *Patinopecten yessoensis*, anaphase I and II occur at around 60 and 100 minutes respectively at a temperature of 9°C (Li et al. 2000). While the meiotic divisions are taking place, the sperm head enters the egg and the male pronucleus migrates to join the female pronucleus on the metaphase plate of the first cleavage spindle and, as such, there is no true zygotic nucleus formed before syngamy (Desilets et al. 1995; Li et al. 2000).

Chromosome counts and karyotypes in early studies on bivalves were usually obtained by observing the chromosomes at meiosis I and II either in released eggs or in male gonad, or during the early mitotic divisions of the embryo (e.g., Beaumont and Gruffydd 1974). However, Thiriot-Quievreux and Ayraud (1982) developed a reliable method of obtaining metaphase chromosomes from bivalve gill tissue, which is now widely used. In order to obtain mitotic chromosomes at the metaphase stage when they are most contracted and most easily identifiable, embryos or gill tissues are treated with colchicine, which arrests mitosis at metaphase. In a brief review, Menzel (1968) gave chromosome numbers of 23 species in 9 families of bivalves and in a more extensive paper Thiriot-Quievreux (1994) reported on the chromosome numbers of all aquatic groups. Generally, chromosome numbers tend to be relatively constant within families and Thiriot-Quievreux (1994) observed the following modal haploid numbers for oysters ($N = 10$), mussels ($N = 14$) and scallops ($N = 19$).

The chromosome numbers of seventeen pectinid species and sub-species are given in Table 10.1 and although many species have the modal number $n = 19$ (Thiriot-Quievreux 1994) there is considerable variation in chromosome number within the group. Some species in the genus *Chlamys* have $n = 19$, (*C. farreri* and sub-spp., *C. distorta* and *C. islandica*) while *C. nobilis* has $n = 16$ and *C. glabra* has $n = 14$. Both *Argopecten* species studied have $n = 16$. Beaumont and Gruffydd (1974) first reported $n = 13$ for *Aequipecten opercularis* but Rasotto et al. (1981) observed $n = 14$ for this species. Insua et al. (1998) confirm without doubt that $n = 13$ for Atlantic coast *A. opercularis*. There are reports of differing chromosome numbers within a single mollusc species (*Nucella lapillus*, Hoxmark 1970) although this is a very unusual occurrence and it is possible that Mediterranean populations of *A. opercularis* could have a different chromosome number from other populations. However, it is more likely that the $n = 14$ reported for

Table 10.1

Chromosome numbers and karyotypes in Pectinidae. Centromere positions t/a = telocentric or acrocentric, s = sub-telocentric, sm = sub-metacentric, m = metacentric. * = described in Brand et al. (1990) as "... 7 metacentric (M) or sub-metacentric (SM) pairs ..."

Mediterranean *C. opercularis* (Rasotto et al. 1981) was incorrect and was due to chromosome breakage, a feature noted by the authors.

How might the variant chromosome numbers in the group have evolved from the modal number? Evolution of chromosome numbers generally depends upon breakage and/or fusion of the chromosomes but these events must involve the centromere, the non-staining, constricted region of the chromosome, which forms the attachment point of the chromosome onto the spindle (White 1973). A chromosome portion with no centromere will generally be lost during cell division since it cannot attach to the spindle.

As the evolutionary relationships between various scallop groups have become better understood (Waller 1991), genus names have been changed to reflect these relationships. For example, *A. opercularis* was previously included in the genus *Chlamys*, but evidence from various sources supported its reassignment to the genus *Aequipecten* (Beaumont 1991a; Waller 1991). More recently, using molecular data from the 16S rRNA molecule, Canapa et al. (2000b) have shown that *Chlamys glabra* clusters with *A. opercularis* (with which it shares a similar chromosome number) and is completely separate from the other *Chlamys* species included in their study (*C. islandica*). It is probable that the inclusion of *C. glabra* in the genus *Chlamys* will be reassessed in the light of these observations.

Species karyotypes are determined by examination of the morphology of the chromosomes, principally by their length and by the position of the centromere which can be terminal or almost terminal (telocentric or acrocentric), median (metacentric) or somewhere in between (sub-telocentric, sub-metacentric). In addition, different staining methods have been employed to identify certain chromosomal regions, for example, silver staining for the nucleolar organising region (NOR), C-banding for localisation of heterochromatin, or G-banding (Thiriou-Quievreux 1994). Modern DNA technology has made possible the localisation of satellites, telomeric sequences and individual genes (e.g., ribosomal RNA genes) using the technique of fluorescent in-situ hybridisation (FISH) (Insua et al. 1998).

Karyotypes have been studied in several scallop species (Table 10.1). The first point to note is that two different authors present two different karyotypes for *P. albicans*. Ieyama (1975) reported 12 telocentric and 7 non-telocentric pairs while Komaru and Wada (1985) identified 14 telocentric and 5 non-telocentric pairs. These differences are most likely due to differences in chromosome preparation methods although different karyotypic races can occur within species. The second observation that can be made is that there is no consistency of centromeric position in the karyotype of those species containing the modal number of 19 chromosome pairs. For example, *P. maximus* has 14 telocentric pairs while *P. yessoensis* has only 3 and *C. farreri farreri* apparently has none. Therefore, evolution of scallop chromosomes appears to have involved considerable changes in chromosome arm lengths without loss of whole chromosomes or centromeres. Where loss of chromosomes has occurred, for example, in *C. nobilis* where $N = 16$, it can be postulated that 'Robertsonian' centric fusion (White 1973) has taken place. This is the process whereby the centromeres of two telocentric or acrocentric chromosomes fuse to produce a single non-telocentric chromosome. Three such fusions within an ancestral karyotype of 19 telocentric pairs would produce 13 telocentric and 3 metacentric pairs of

chromosomes which is the precise karyotype reported for *C. nobilis* by Komaru and Wada (1985). Of the two other species having $n = 16$, no karyotype data are published for the bay scallop *A. irradians* and the karyotype for Chilean scallop, *A. purpuratus* (Brand et al. 1990) is very different with only 4 telocentric chromosome pairs. However, bearing in mind that there is evidence of considerable evolutionary changes in chromosome arm lengths in scallop species with the modal number, it is not surprising to observe no clear evidence of centric fusion in other species.

The most detailed karyotypic study in any of the pectinids is that by Insua et al. (1998) on *A. opercularis*. They demonstrated that the C-banding pattern showed heterochromatin blocks of differing staining intensity in various regions of all the chromosomes and this assisted in the identification of some specific chromosomes. In contrast, C-banding in mussels and oysters is usually observed in telomeric or metameric positions, and not on every chromosome. A single strong consistent NOR was located to a particular telocentric chromosome (No. 7) and this was confirmed by FISH localisation of an 18S-28S rRNA probe to the same position. Finally, in the first such study in molluscs, the 5S rRNA gene was located in one arm of the largest metacentric chromosome (No. 1) (Insua et al. 1998). Telomeric sequences have now been isolated and sequenced from the bay scallop (*A. i. irradians*) by Estabrooks (1999) and these will make useful tools for the study of the karyotype of this species. In addition, because the number of repeats of telomeric sequences are related to senescence, and the bay scallop is essentially an annual species, these sequences will be valuable in the study of longevity in scallops.

10.2.2 Ploidy Manipulation

Artificial changes in ploidy can be induced during the egg maturation divisions in fish and shellfish. The principle technique used in ploidy manipulation involves allowing chromosome division (karyokinesis) but preventing cytoplasmic division (cytokinesis) at meiosis I, meiosis II or first cleavage division. This can be achieved by subjecting eggs to a temperature shock, a pressure shock or to chemical action (cytochalasin B (CB) or 6-dimethyl amino-purine, (6-DMAP)) at the appropriate time during the maturation or first cleavage divisions. Triploids are produced by suppression of either meiosis I or meiosis II and tetraploids by suppression of first cleavage. A further technique is the use of irradiated spermatozoa, together with suppression of meiosis I, meiosis II or first cleavage, to produce gynogenetic diploid offspring. Four main methods have been employed to identify polyploid individuals; direct chromosome counting in early embryos, flow cytometry of larvae or adults, DAPI staining or electrophoresis of juveniles or adults. For a review of ploidy manipulation in molluscan shellfish, see Beaumont and Fairbrother (1991) where methods and consequences are more fully discussed.

Triploid shellfish exhibit features of value to the aquaculturist. During gametogenesis in diploid individuals, homologous pairs of chromosomes synapse early during meiosis I, but in triploids, pairing of the chromosomes is likely to be interfered with by the presence of a third homologous chromosome. For this reason, triploid individuals are expected to be sterile and evidence from triploid finfish and bivalves

indicate that the sterility generally manifests itself early during gonad development, producing animals with small or very reduced gonads (Beaumont and Fairbrother 1991). Because less energy is utilised in gonad production, adult triploids are expected to have a higher somatic production than mature diploids and this extra meat weight is of economic importance to aquaculture. In the case of oysters, the lack of extensive reproductive tissue also enables year-round marketing (Allen 1988). A further advantage of sterility is that triploids of exotic species can be cultivated without danger of spawning under cultivation and competing with indigenous species. Recently, evidence of reversion to diploidy in older oysters, which were initially triploids has cast doubt on the value of triploids for this purpose (Shatkin et al. 1997; S. K. Allen, pers. comm.).

Methods for inducing triploidy by physical or chemical shock are seldom 100% effective. Therefore the potential value of producing tetraploid individuals is that they can be used as broodstock to provide diploid gametes which, when used with haploid gametes from diploids, will give 100% triploid offspring. In principle, tetraploids can be produced by suppression of the first cleavage division and this has proven to be a practical method for producing tetraploid fish. However, attempts to use this method in bivalves have always failed: although small numbers of tetraploid embryos can be produced, these do not survive to maturity. Guo and Allen (1994) have nevertheless developed a method for production of tetraploid oysters (*C. gigas*), which relies upon suppression of meiosis I in eggs produced by triploid females. Although only a few eggs are produced, and only a small proportion of the treated eggs produce tetraploid embryos, many of these tetraploid embryos do survive to maturity and are effective as broodstock (Guo et al. 1996).

Triploids have been produced in a number of pectinid species: *A. irradians* (Tabarini 1984), *P. maximus* (Beaumont 1986; Clarke 1991), *C. nobilis* (Komaru et al. 1988; Komaru and Wada 1989, 1991; Zeng et al. 1995), *M. varia* (Baron et al. 1989), *A. purpuratus* (Toro et al. 1995) and *Argopecten ventricosus* (= *circularis*) (Ruiz-Verdugo et al. 2000).

The cytochalasin B (CB) chemical method was used in most triploid induction studies on scallops. Toro et al. (1995) used heat shock successfully on *A. purpuratus* and Komaru and Wada (1989, 1991) tried pressure treatment on *C. nobilis*, but with limited success. As with other bivalves (Beaumont and Fairbrother 1991), a major side effect of the use of CB was a significant reduction in the number of larvae produced (Tabarini 1984; Beaumont 1986; Baron et al. 1989; Ruiz-Verdugo et al. 2000).

Higher overall heterozygosity is predicted in triploids compared with diploids and, because multi-locus heterozygosity (MLH — see later) is often positively correlated with size at age in many bivalves, then we might expect to detect faster growth in triploids compared with diploids. In studies where reliable data on larval growth of triploids have been collected, results are equivocal. For *P. maximus*, Beaumont (1986) and Clarke (1991, see Beaumont 2000a) found that 3N larvae grew significantly faster than 2N larvae, but no such trend was evident when comparing growth of 3N and 2N larvae of *M. varia* (Baron et al. 1989) or *A. purpuratus* (Toro et al. 1995). There has been some uncertainty in the bivalve literature about whether meiosis I triploids might have higher heterozygosity than meiosis II triploids (Stanley et al. 1984; Beaumont and Kelly 1989; Beaumont and Fairbrother 1991; Hawkins et al. 1994), but this actually depends on

recombination rates of the loci which are being scored (Beaumont 2000a). Across the genome as a whole there is probably little difference between the heterozygosity of meiosis I and meiosis II triploids. Also, the detection of slight, and barely significant differences in growth rates between cohorts of 3N and 2N larvae will depend on the proportion of the 3N cohort, which are actually triploid (often <80%). Finally, speculation about any marginal relationship between heterozygosity and growth in triploids, relative to diploids, may be outweighed by the potential effect of polyploid gigantism as proposed by Guo and Allen (1994) and Guo et al. (1996).

Twelve month old triploid *A. irradians* had a significantly higher mean adductor muscle weight and total body tissue weight than their diploid counterparts (Tabarini 1984). Although shell height and length were not significantly different, shell inflation was significantly greater in triploids compared to diploids and, as observed in other bivalves, the majority of triploid scallops failed to ripen or spawn. The effect of triploidy on the adductor muscle index was not significant at 6 months but only became significant after gonad growth had occurred in the diploids. A similar pattern was seen in triploid *C. nobilis* (Komaru and Wada 1989) with significant differences in meat weight and shell width between 3N and 2N scallops only becoming evident at 14 months. In the case of *A. ventricosus* (= *circularis*) (Ruiz-Verdugo et al. 2000), performance of 4 to 14 month old triploid scallops was significantly better than diploids in all traits measured (shell dimensions, tissue weights, muscle index) except for gonad index, which was significantly depressed in triploids as the scallops reached maturity. Interestingly, the normal hermaphrodite status of this species was radically distorted with all triploids eventually becoming female (Ruiz-Verdugo et al. 2000).

These studies have demonstrated that significant increases in weight or size of triploid over diploid scallops are only detectable when triploid sterility becomes evident. This suggests that neither increased heterozygosity, nor polyploid gigantism play a major role in increased size of triploid scallops. Considering the impressive effect of triploidisation on muscle weight and size, the aquacultural potential of triploids scallops is high if it is the “roe-off” market (mainly the USA), which is targeted. However, there is no advantage to culturing triploid scallops for the “roe-on” or whole-body market, in spite of their greater muscle weight, because of the underdeveloped gonad and its potential discolouration in triploids (Ruiz-Verdugo et al. 2000).

10.3 GENETIC MARKERS AND POPULATION GENETICS

10.3.1 Genetic Markers

In order to study genetic variation at the individual or population level it is necessary to use markers of known genes or of portions of the genome. The development of markers of protein variation — allozymes — in the 1960's paved the way for the first extensive studies of the genetics of non-human organisms, which like the scallop, were neither important agricultural crops (e.g., maize) nor amenable to genetic studies by virtue of ease of handling and short generation time (e.g., fruit flies).

Part of the motivation for population genetic studies in scallops came from the relative success that allozyme studies were having in addressing population and species level problems in other marine bivalves, particularly mussels and oysters. Moreover, in several bivalve species, certain interesting genetic phenomena such as heterozygote deficiency and the correlation between degree of heterozygosity and growth or viability, had become apparent. These studies not only increased our understanding of the biology of the species concerned, but also made substantial contributions to several fundamental problems in population genetics and evolution, such as the nature of heterosis, the genetic control of variation of flux along enzymatic pathways, the physiological basis of variable growth. For a wider discussion of these phenomena see reviews by Zouros and Pogson (1994), Gaffney (1994) and Britten (1996) as well as papers by Koehn et al. (1988), Hawkins et al. (1994) and Hedgecock et al. (1996).

In the last 25 years of the 20th Century there have been several significant developments in DNA technology which have led to the routine use of several novel genetic marker systems based directly on variation at the level of the DNA molecule (Beaumont and Hoare 2003). The ways in which allozymes, and these new markers, have been used to address questions on the genetics of scallops will be presented and discussed following an outline of the principle techniques, which have been employed.

10.3.1.1 Allozymes

The demonstration of electrophoretic separation and identification of proteins — usually enzymes — on gels introduced a novel and simple methodology for investigating genetic variability in individuals and populations. Soluble proteins from tissue samples are placed at an origin point on a flat bed gel of starch or polyacrylamide and an electric current passed through the gel. The proteins, which are charged molecules, migrate along the gel and are separated according to their different mobilities. Identification of the final position of the proteins or enzymes is achieved by the use of general protein or specific enzyme stains.

Mutations of a gene at a locus may alter the charge, size or configuration of the protein product of that locus and these alterations will generally affect the mobility of the protein on a gel. Thus, the protein products of different alleles at a locus can be detected. Homozygotes will exhibit a single band on the gel and heterozygotes of monomeric enzymes, two bands. Banding patterns for heterozygotes of dimeric and other oligomeric enzymes reflect the random association of sub-units and consist of three or more bands. Thus, electrophoresis of a sample of individuals from a population can provide an estimate of genotype frequencies, and, by simple calculation, allele frequencies at protein encoding loci.

10.3.1.2 DNA methods

Routine procedures exist for the extraction of DNA from animals and its separation from other cellular constituents (Sambrook et al. 1989). Isolated DNA can be “cut and pasted” using restriction enzymes (REs), which cut at specific nucleotide sequence sites,

and DNA ligases, which enable fragments of DNA to be joined. DNA can be stained by ethidium bromide or by radiolabelling, which is much more sensitive. However, in order to visualise a fragment of DNA, or to sequence it, the fragment needs to be replicated and millions of copies produced. This can be achieved by two main methods. Firstly, DNA can be cloned in bacteria by inserting the DNA fragment into the DNA molecule of a vector. The vector can be either a plasmid or a virus (phage), which can enter bacterial cells and be replicated along with the bacteria during its normal growth. Thus, bacterial colonies containing millions of copies of particular fragments can be produced. The second method for copying, or amplifying DNA is the polymerase chain reaction (PCR) technique, which uses a pair of short (15–30 bp) oligonucleotide primers each complementary to one end of the target DNA. These are extended towards each other by a thermostable DNA polymerase in a reaction cycle of three parts: denaturation, primer annealing and polymerization. The DNA is first denatured at 95°C, an annealing step follows at 55°C, which allows the primers to bind, and a final polymerization step takes place at 72°C. The reaction mixture, held in a microtube and placed in the PCR machine, contains the template DNA, primers, DNA polymerase, Mg^{2+} , a mixture of oligonucleotides (dNTPs) all suspended in a buffer. In each cycle, which takes only a few minutes, the number of copies is doubled and so millions of copies are produced after 30 to 40 cycles. For an overview of these methods see Turner et al. (1997).

Mitochondrial (mt)DNA is a circular molecule present in all mitochondria. The basic advantages of mtDNA for population and evolutionary studies are the ease with which it can be isolated from the nuclear DNA, its uniformity in the individual organism, its relatively small size in animals (16–17 kb — but see later), and its uniparental inheritance (Meyer 1994). The finding that animal mtDNA evolves at a much higher rate than single copy nuclear DNA adds to this list of desired properties. Simple tissue extractions will already contain millions of copies of mtDNA and because mtDNA can be separated from nuclear DNA by centrifugation methods, subsequent whole molecule mtDNA amplification is not usually required.

10.3.1.3 DNA based markers

10.3.1.3.1 Restriction fragment length polymorphism (RFLP)

Any amplified length of DNA can be incubated with a suite of REs each of which has a different target sequence. Depending on the RE cut sites present, a number of fragments will result, which can be separated on the basis of length using gel electrophoresis. Mutations, which affect the sequence at any RE cut site, will change the length of fragments produced and these polymorphisms are RFLPs.

10.3.1.3.2 Random amplified polymorphic DNA (RAPDs)

PCR primers for amplifying known sequences of DNA are usually 15–30 bp long. If the primers are much shorter than this then there is the chance that other random regions of the genome will be amplified in addition to the targeted sequence. The RAPD method

exploits this by subjecting template DNA to PCR with a single primer of 10 bp in length. Wherever this primer is complementary to opposite strands of DNA separated by less than 2–3 kb, an amplified fragment will be produced so the final PCR product will contain from none to several fragments of different sizes. Fragments are separated by agarose gel electrophoresis and bands can be sized and scored. Screening DNA with a range of 10 bp primers enables large numbers of randomly amplified fragments to be scored. Where a mutation occurs at a primer site, preventing the primer from annealing, the normal fragment product will be missing and a polymorphism is recognised by the absence of a band on the gel.

10.3.1.3.3 Microsatellites

Microsatellites are short (<1 kb) regions of the genome containing a repeated motif consisting of 1 to 5 base pairs. Genetic variability results from the variation in the number of these repeats and the detection of this variation depends on sizing the fragment of DNA (containing the microsatellite region), which is PCR-amplified from the raw DNA of an individual. Identification and isolation of microsatellite loci is a complex procedure (see Estoup and Angers (1998) for details) but once primers have been developed for the loci then the routine screening of genotypes is rapid, and can be automated to some extent by using an automatic sequencer to size the alleles.

10.3.1.3.4 Amplified fragment length polymorphism (AFLP)

The AFLP method (Vos et al. 1995) can provide a large number of reliably reproducible size fragment-markers from DNA of unknown sequence. Extracted DNA is cut using a pair of restriction enzymes, which leave cohesive (sticky) ends, one a frequent (4 base) cutter, the other a rare (6 base) cutter. The majority of fragments produced will have 4 base-cut ends, the minority will have 6 base-cut ends and the remainder will have 6 base - 4 base ends. Two oligonucleotide “adapters” designed to attach to the cohesive cut ends of both the 6-base and 4 base fragment terminals are then ligated to the resulting fragments. These adapters are used as the basis for polymerase chain reaction (PCR) primers, which are also designed to overlap with the DNA fragment by one, two or three specified bases. The primer for the less frequent (6 base) cut adapter is radiolabelled before PCR amplification and the resulting fragments are separated on polyacrylamide gel and visualised by autoradiography or fluorescence. By varying the number of specified bases on the primers the number of fragments amplified can be controlled. Typically 50-100 restriction fragments can be identified and separated in a single run of the AFLP method. Although there are currently no publications on the use of AFLP in scallops, this method is included here because it has been used in China to investigate the reduction of genetic variation in 2 selected populations of *C. farreri* compared with a wild population (Z. Yu, pers. comm.) and there is little doubt that AFLPs markers will be used extensively in the near future in the search for quantitative trait loci (see section on quantitative genetics).

10.3.1.4 Mitochondrial DNA in scallops

An initial study on *P. magellanicus* showed that the mtDNA molecule was much larger than the expected 16–17 kb, reaching 31–42 kb in length, and it was also noted that there was considerable variation in size between the mtDNA from different individuals (Snyder et al. 1987). It was discovered that the main cause of this variation was the variable number of copies of an element that occurred in direct tandem repeats in all mtDNA molecules of this species. This 1.47 kb repeat element was sequenced by La Roche et al. (1990) and it was shown to occur as 2 to 8 copies per molecule. More recent studies have revealed further complexity with 3 separate regions in *P. magellanicus* mtDNA which exhibited tandem length repeat polymorphisms: locus I (1450 bp), locus II (250–1000 bp) and locus III (100 bp) (Fuller and Zouros 1993). Locus I and II overlap slightly, which complicates analysis, but locus III occurs on the opposite side of the molecule (Cook and Zouros 1994). Although mtDNA size variation has been identified in other invertebrates (Moritz et al. 1987; Gjetvaj et al. 1992), the presence of at least 2 (possibly 3) independent repeat sequence polymorphisms located in different regions of the mtDNA is a very rare phenomenon (Cook and Zouros 1994) and has been demonstrated only in *P. magellanicus* and one other scallop species, *C. islandica* (Gjetvaj et al. 1992). Using mtDNA extracted from 2 parents and their 1 year old offspring, Cook and Zouros (1994) demonstrated that there was a very high mutation rate associated with locus I and locus II because 15% of the offspring had mtDNA haplotypes which differed from what could be detected in the mother. Although mtDNA is expected to be under strong selection for economy of size, there is no evidence that the extensive size polymorphisms in *P. magellanicus* is anything other than selectively neutral (Zouros et al. 1992).

MtDNA repeat sequence variation has been identified in several other scallop species, namely *P. maximus*, *Crassodoma gigantea*, *A. opercularis*, *Chlamys hastata*, *C. islandica* and *P. yessoensis* (Gjetvaj et al. 1992; Rigaa et al. 1993, 1995; Boulding et al. 1993). Gjetvaj et al. (1992) used the *P. magellanicus* repeat motif to test for its presence in other species, but found no hybridisation product. Rigaa et al. (1993, 1995, 1997) studied length variation in the mtDNA of *P. maximus* in detail and identified a sequence of 1,586 bp, which occurs as 2 to 5 repeated units. They compared this repeat region with the locus I (1.6 kb) repeat in *P. magellanicus* (Fuller and Zouros 1993) and, like Gjetvaj et al. (1992), found no clear similarity. Nevertheless, some homology was evident when comparing the nucleotide content of different domains: both species exhibit an Adenine+Thymine-rich region, and an upstream Guanine-rich region preceded by a potential hairpin structure (Rigaa et al. 1995). Furthermore, this bears some similarity to the 1.2 kb non-coding region of the *Mytilus edulis* mitochondrial genome (Hoffman et al. 1992) and suggests that there may be systematic value in further studies of these repeat regions in scallop mtDNA (Rigaa et al. 1995).

From the point of view of using mtDNA as a genetic marker the extensive length variation of this molecule in scallops presents difficulties. The numbers of repeats do not appear to be population specific in *P. magellanicus* (Fuller and Zouros 1993) or in *P. yessoensis* (Boulding et al. 1993), although when the structure of the molecule and the

position and size of the repeat motif is better known some direct RFLP population analysis is possible as demonstrated by Rigaa et al. (1997) in *P. maximus*. The main method employed to get usable genetic markers out of scallop mtDNA has been to clone and sequence a part of the molecule, which is not in the repeat region and use PCR to amplify this fragment directly (Boulding et al. 1993; Wilding et al. 1997; Heipel et al. 1999).

Although most scallop species so far investigated have mtDNA repeat sequence variation, *A. irradians* and *Argopecten gibbus* have a fixed length mtDNA molecule of around 16.5 kb without repeat sequences (Gjetvaj et al. 1992; Blake and Graves 1995) and therefore are amenable to standard mtDNA RFLP analysis. Seyoum et al. (2003) have developed a very effective mtDNA marker to be used as a genetic tag for *A. irradians* in Florida.

10.3.1.5 Types of data produced by different markers

Allozymes and microsatellites produce co-dominant genotypic data such that homozygotes and heterozygotes can be unambiguously identified (except in the case of null alleles, see later). On the other hand, RAPDs and AFLPs produce dominant data where one homozygote (band-band) and the heterozygote (band-no band) are indistinguishable. RFLP data provide information on sequence differences between variants based on RE cut sites and can be quantified as nucleotide differences. Because mtDNA is essentially a haploid clone (as opposed to the diploid, sexually reproduced nuclear DNA) analysis is based on nucleotide, or haplotype divergence.

10.3.1.6 Analysis of data

Once data on the numbers and proportions of different genotypes at a co-dominant marker locus (e.g., allozyme or microsatellite locus) are available for a sample of organisms, the frequencies of the alleles at that locus can be estimated. The Hardy-Weinberg model predicts the expected genotype frequencies based on these estimated allele frequencies. For the simplest case, consider a locus with two co-dominant alleles A and B present at frequencies p and q where $p + q = 1$. The Hardy-Weinberg model states that the frequency of the genotypes AA, AB and BB in the next generation will be p^2 , $2pq$ and q^2 , respectively. Significant deviations from genotype frequencies predicted by the Hardy-Weinberg model may be produced by a number of factors such as natural selection, migration into, out of or between populations, mating structure, or the presence of non-staining protein products of an allele (null allele). Early studies generally used χ^2 Goodness of Fit tests to detect significant deviations from the model, but nowadays exact tests are used (Raymond and Rousset 1995).

In early literature relating to bivalves, the degree of deviation of genotype frequencies from Hardy-Weinberg expectations at a locus was commonly denoted by Selander's (1970) index "D" where:

$$D = (H_o - H_e)/H_e \quad (1)$$

Where, H_o = observed numbers of heterozygotes and H_e = expected numbers of heterozygotes according to the Hardy–Weinberg model and

$$H_e = 1 - \sum x_i^2 \quad (2)$$

Where, x_i is the frequency of the i^{th} allele. A negative value of Selander's (1970) D indicates a deficiency of heterozygotes. Although Selander's (1970) D has been used in some bivalve literature, the much better and more widely used statistic is Wright's (1951) F , sometimes called the inbreeding coefficient.

Wright's F statistics (Wright 1951) provide a measure of deviation from the Hardy–Weinberg model for each allele at a locus, in individual sub-populations (F_{is}) and for the total population (F_{it}) and are calculated as:

$$F_{is} \text{ or } F_{it} = (H_e - H_o) / H_e \quad (3)$$

Positive values of F_{is} and F_{it} indicate a deficiency of heterozygotes against the model; negative values an excess of heterozygotes. For each locus, if all the sub-populations are in agreement with the Hardy–Weinberg model, and share the same alleles at the same frequencies, then the mean of F_{is} will equal F_{it} . However, if one or other sub-population differs in allele frequency, or is in disagreement with the Hardy–Weinberg model, then mean F_{is} will differ from F_{it} . This feature is used to calculate the statistic F_{st} , which is a measure of the degree of differentiation between sub-populations where:

$$F_{st} = (F_{it} - \text{mean } F_{is}) / (1 - \text{mean } F_{is}) \quad (4)$$

When there is no sub-population differentiation, F_{st} is zero. Values of F_{st} above zero indicate differentiation and the significance of this differentiation can be calculated. F_{st} can further be related to the size of the sub-populations and the migration rate between them such that:

$$F_{st} = 1 / (1 + 4Nm) \quad (5)$$

Where N is the effective sub-population size and m is the proportion of that effective population size that migrates between sub-populations each generation. The effective population size is the number of individuals, which actually make a genetic contribution to the next generation and therefore excludes immature or otherwise infertile organisms.

It is important to note that the assumptions made in the development of the F statistics are, amongst others that all sub-populations are of equal size, and that they each exchange equal numbers of migrants with all other sub-populations at each generation (Wright 1951). Clearly, this is seldom the case in the wild and particular caution is required in extrapolation of F_{st} to statements about Nm , the number of migrants between sub-populations.

Although the significance of allele frequency differences between populations can be simply tested by Contingency Table χ^2 tests (more recently, more accurately, by exact

tests), and F_{st} can provide an estimate of potential sub-population structure, Nei's (1978) genetic identity (I) and distance (D) provide further insight into the relative degree of differentiation among populations. Genetic identity is computed for any pairwise combination of populations according to:

$$I = \sum(P_{ix} \cdot P_{iy}) / \sqrt{\sum(P_{ix}^2 \cdot P_{iy}^2)} \quad (6)$$

where P_{ix} is the frequency of allele i in population x and P_{iy} is the corresponding frequency in population y . Genetic distance, D is related to genetic identity (I) according to the formula:

$$D = -\ln I \quad (7)$$

Values of Nei's (1978) D for allozyme data are interpreted as the net number of codon substitutions per locus that have accumulated since separation of any two populations. The rate at which this "molecular clock" accumulates mutations is still a matter of debate (Avice 1994) but Nei (1978) suggests that a value of $D = 1.0$ implies a separation of 5 million years. In the *Drosophila willistoni* group of fruit flies, for example, the mean genetic distance is 0.031 for conspecific populations, 0.229 for semi-species, 0.660 for sibling species and 1.044 for full species (Ayala et al. 1974).

10.3.2 Overall Genetic Variation

Two indices of genetic variation are generally employed for allozyme data; P , the proportion of polymorphic loci and H_o , the mean observed heterozygosity per locus. These indices are also relevant for microsatellite loci. Table 10.2 lists values of P and H_o for a number of pectinid species. In species such as *P. yessoensis*, where some estimates show low values of P and H_o (Nikiforov and Dolganov 1982; Balakirev et al. 1995) this is possibly due to the inclusion in these studies of a high proportion of non enzymatic loci, which are generally less variable than enzymatic loci (Smith and Fujio 1982). In the case of *Lyropecten nodosa* and *Euvola ziczac* (Coronado et al. 1991), which have the lowest values, the authors suggest that gene duplication may have increased the number of loci, but that these loci are mainly monomorphic. An alternative suggestion is that the populations from which these hermaphroditic species were sampled were inbred due to extensive self-fertilisation. The values of P and H_o for the microsatellite loci in *P. magellanicus* illustrate the very high level of variation characteristic of these genetic markers compared with allozymes.

Considering all the scallop species for which we have allozyme data (Table 10.2), the mean of P is 0.49 and the mean heterozygosity is 0.164. These values are higher than for other bivalves (Ahmad et al. 1977; Buroker 1980; Buroker et al. 1983) and for invertebrates in general (Hedrick 1985). It is important to bear in mind that these estimates of genetic variability are taken from studies based on relatively few gene loci (10–25) and may therefore be rather unreliable estimates of overall genomic variability.

Table 10.2

Estimates of proportion of allozyme loci (except ^b), which are polymorphic (P) and average levels of observed heterozygosity (Ho) in scallop species and other bivalves. ^a = values calculated from data in paper; ^b = microsatellite loci; ^c = probably *Argopecten irradians concentricus* - collected from North Carolina.

Theoretically from an aquaculture point of view, high genetic variability should be an advantage since overall genomic heterozygosity is associated with increased vigour (Lerner 1954). Nevertheless, in practice, certain bivalves, such as the European mussel, which appear to have a low overall level of genetic variability, are able to survive and grow vigorously both in culture and in a wide range of environmental conditions. By comparison, European scallop species tend to grow less vigorously and to be more problematical to rear in culture than mussels.

10.3.3 Genetic Differentiation of Populations

One of the more valuable contributions of electrophoretic assays of genetic variation is in the area of taxonomy and population subdivision. Before the advent of allozyme electrophoresis, taxonomic studies relied almost exclusively on morphological characters. These characters are useful for discriminating among species, but are of little use for the study of differences between geographic populations or for the study of the related problems of hybridisation and gene flow. Examples of the use of allozyme data for such applications in marine bivalves can be found in Skibinski et al. (1983), Koehn et al. (1984), Varvio et al. (1988), McDonald et al. (1991) and Gosling (1992).

10.3.3.1 *Placopecten magellanicus*

Zouros and Gartner-Kepkay (data cited in Beaumont and Zouros 1991) used variation at 5 polymorphic allozyme loci to assess the level of sub-population structure of *P. magellanicus* with samples taken throughout its range extending from the Bay of Fundy and the coast off Nova Scotia to the Southern end of Georges Bank. Contingency Table χ^2 tests across all populations revealed significant allele frequency differences at the octopine dehydrogenase (*Odh*) and the 6-phosphogluconic acid dehydrogenase (*Pgd*) loci but not at the other three loci. However, as in other scallop allozyme studies published before the mid 1990s, no Bonferroni correction for multiple tests of the same hypothesis (type I error) was applied (Lessios 1993). When such a correction is applied to these data, only the *Odh* value remains significant.

Nei's (1978) genetic distances (*D*) for all populations are given in Table 10.3 and the last column of the table estimates the 'average' distance of each population. This represents the distance that one would obtain for this population if all other populations were combined into one. The sample from Georges Bank South (number 4), which is the southernmost sample, showed the largest genetic distances in most pairwise comparisons (average distance $D = 0.0078$). Even so, these genetic distances are typical of conspecific populations of other species and they provide no evidence for severe or prolonged isolation of these populations from each other. Nevertheless, the significant differentiation in allele frequencies at one of the five loci suggests that the various geographic populations of this species should not be considered as parts of a single randomly mating population. However, the only locus responsible for the significant differentiation among geographic populations is *Odh* for which, as discussed later, there are good reasons to suspect strong selection pressures.

P. magellanicus allozyme data from Volckaert et al. (1991) also show low values of Nei's (1978) genetic distance, ranging from 0.002 to 0.004, when comparing a shallow water (Damariscotta River) population, a neighbouring deep water (Gulf of Maine) population, and two Canadian populations from Nova Scotia (Foltz and Zouros 1984) and New Brunswick (Volckaert and Zouros 1989). Beaumont and Zouros (1991) later noted earlier studies confirmed that there is very little identifiable allozyme-genetic variation between populations of *P. magellanicus*, and they also provide no evidence for an allozyme-genetic basis for the physiological and biochemical differences exhibited by

Table 10.3

Genetic distances (D , Nei 1978) among eight populations of *Placopecten magellanicus* based on allele frequencies at five enzyme loci (modified from Beaumont and Zouros 1991). The last column gives the average genetic distance of each population from all others. Populations: 1 = Middle Grounds, 2 = Browns Bank, 3 = Bay of Fundy, 4 = Georges Bank (South), 5 = Second Peninsula, 6 = Georges Bank (North), 7 = Grand Manan, 8 = Georges Bank (North East).

	2	3	4	5	6	7	8	mean D

7							0.006	0.004
8								0.006

shallow water and deep water populations in Maine. These authors report a significant *Odh* allele frequency difference between the deep and shallow water populations, but this is not significant following Bonferroni correction.

The population structure of *P. magellanicus*, deduced from allozyme studies, is therefore one of a geographically fragmented species whose constituent populations exchange individuals at a rate that prevents the accumulation of marked genetic differentiation. What genetic heterogeneity there is probably results from a combination of reduced migration rates over geographic distance, and varying selection pressures.

Patwary et al. (1994) developed a suite of RAPD markers for *P. magellanicus* and tested them for Mendelian inheritance, but did not carry out an extensive study of population structure. Differences in frequencies of bands in samples from different locations were noted but not quantified or further analysed. They did establish that great care was required initially to ensure that scored bands could be reliably repeated and pointed out that though the RAPD technique was, in principle, a speedy method for estimating genetic structure, the time taken to ensure reliability, and the fact that the data are not co-dominant, were major drawbacks. Gjetvaj et al. (1997) published primers for seven microsatellite DNA markers in *P. magellanicus* and confirmed their Mendelian inheritance using a full-sib family. They did not use the markers to investigate population structure, but pointed out the power of these markers as tools for such studies by virtue of their high variation and the fact that individual larvae could be genotyped. One of the loci has already been used in a deep mesocosm study of larval behaviour (Manuel et al. 1996).

10.3.3.2 *Patinopecten* (= *Mizuhopecten*) *yessoensis*

Both Russian and Japanese groups have studied the population structure of *P. yessoensis* across much of its range using allozymes (Kijima et al. 1984; Balakirev et al. 1995; Dolganov 1995; Pudovkin and Dolganov 1995; Dolganov and Pudovkin 1997, 1998). Data from some of these studies, brought together and re-analysed by Dolganov and Pudovkin (1998), have indicated that there are several relatively distinct populations of *P. yessoensis* around the Sea of Japan and the Sea of Okhotsk. A single sample taken from Furunhelm Island, just south of Posjet Bay, Primorye, appeared different from all other groups, while an essentially panmictic group (the Primorye group) extends from Posjet Bay along the Russian coast to Chikhachev Bay in the North of Primorye. Two distinct groups inhabit Terpenija Bay and Aniva Bay in Sakhalin Island, to the North of Japan. Earlier analysis by Kijima et al. (1984), which apparently showed genetic differentiation of samples from the North coast of Hokkaido, was criticised by Dolganov and Pudovkin (1998). In this later analysis, Kijima et al.'s (1984) samples from the North coast of Hokkaido grouped together with Dolganov and Pudovkin's (1998) Kuril Island samples with characteristic allele frequencies at most loci to form the fifth population group of *P. yessoensis*. Although there are significant allele frequency differences between these 5 groups, Nei's (1978) mean pairwise genetic distances are not particularly large and range from 0.003 to 0.037. It is therefore probable that there is a certain amount of larval interchange between some of these groups. Following the expectation that significant linkage disequilibrium might be detectable in populations, which were sharing recruitment from two different sources, Pudovkin et al. (1998) tested the Primorye group and the Furenhelm Island sample for linkage disequilibrium at six polymorphic loci. They found a significant disequilibrium in the Furenhelm sample when only the Primorye data were used, but this disequilibrium was not significant when analysed in the context of data from all five groups of scallops (Dolganov and Pudovkin 1998).

Boulding et al. (1993) used analysis of mtDNA to investigate population differences between a stock of *P. yessoensis* imported into, and bred in Canada for 3 generations and two populations in Japan, one of which was the source of the Canadian importation. As noted earlier, length variation caused by tandem repeat regions is common in the mtDNA of most scallop species so these authors used PCR amplification of length-invariant regions of the mtDNA to provide fragments for RFLP analysis. Pure mtDNA was extracted, cut into fragments, and then the fragments were cloned. Clones were sequenced and tested against known (at that time) conserved regions of the mtDNA of other animal groups. Four sequences were selected as having no potential length-variant component and pairs of primers were designed for these sequences. Following RFLP analysis of the PCR amplified products of these sequences, 11 mtDNA haplotypes were identified. Comparison of the frequencies of these haplotypes revealed no significant difference between either of the Japanese populations or the imported Canadian sample. Although the main purpose of Boulding et al.'s (1993) approach was to investigate potential bottleneck effects from the importation of the Japanese scallop into Canada (Beaumont 2000b), the results support the expectation that *P. yessoensis* from Mutsu Bay

(Aomori) and Uchiura Bay (Hokkaido), because of their geographical closeness, are likely to be part of a single panmictic population.

Using 3 of Boulding et al.'s (1993) mtDNA markers, Wilbur et al. (1997) analysed genetic variation in a *P. yessoensis* sample from Amursky Bay in Peter the Great Bay (Siberia, Primorye) and compared this with Boulding et al.'s (1993) data on Japanese populations and the Canadian imported stock. The results suggested two rather contrasting situations. Basically, there was very little divergence between the 26 mtDNA haplotypes identified, that is, all haplotypes differed from each other by no more than one or two site changes. Thus, there is no evidence for a deep split at some time in the past between the groups. On the other hand, a significant haplotype frequency difference was evident between the Primorye sample and all others suggesting that there has been little recent mixing between the Japanese and the Primorye population. This result supports the findings of allozyme studies (Dolganov and Pudovkin 1998) and adds strength to the idea that the Primorye population should be considered as a separate stock to populations in Japan.

10.3.3.3 *Pecten maximus*

There have been two extensive allozyme population genetic studies of *P. maximus* but neither reveals any evidence of sub-population structure. Using 8 polymorphic loci across 13 populations from the UK and France, Beaumont et al. (1993) reported a range of pairwise Nei's (1978) genetic distance values of 0.003 to 0.031. Similar values ranging from 0.007 to 0.045 were found by Wilding et al. (1998) using 7 polymorphic loci across 9 populations.

Wilding et al. (1997) developed genetic markers from the mitochondrial DNA of *P. maximus* by extracting and cloning fragments of the mtDNA, which did not contain length-variable regions (Rigaa et al. 1993, 1995). Following primer development, the marker, *Pma1* (a 2kb *EcoRI* - *HindIII* fragment), was amplified by PCR from samples of *P. maximus* DNA from 9 sites. Following cutting with 6 restriction enzymes 59 different composite haplotypes were identified and sequence divergence values derived from these were used to estimate genetic difference between the populations. Incomplete data from a second marker (*Pma2*, a 3.8kb *HindIII* - *HindIII* fragment) were also analysed. All the UK and French coast samples were essentially indistinguishable from one another and only one site, Mulroy Bay, Ireland, showed a significant difference from all other sites. Earlier studies on the different physiology and reproductive patterns of *P. maximus* from St. Brieuc and the Rade de Brest had suggested that these populations might be genetically distinct (Cochard and Devauchelle 1993; Mackie and Ansell 1993). These sites were included in Beaumont et al.'s (1993) and Wilding et al.'s (1997, 1998) studies and showed no differentiation. Rigaa et al. (1997) also compared populations of *P. maximus* from St. Brieuc, the Rade de Brest, and the Glenan Islands using whole mtDNA RFLP analysis. No significant differences were detected between the populations.

Heipel et al. (1999) used Wilding et al.'s (1997) marker *Pma1*, and a second marker developed from another non-length-variable region of the mtDNA, to investigate population differentiation amongst more localised populations around the Isle of Man

(UK) with outlying samples from Plymouth and Mulroy Bay. Their nucleotide divergence results showed Mulroy Bay and one of the Isle of Man samples clustering separately from the rest, but these two samples nevertheless each exhibited several unique and rare haplotypes implying that they were actually quite genetically distinct. A parallel study on these same population using RAPDs (Heipel et al. 1998) showed a clear distinction between the Mulroy Bay population and all others. In addition, the data show some structuring amongst geographically close *P. maximus* samples taken from around the Isle of Man, something which had not been detected in mtDNA or allozyme studies for this species. As previously mentioned (Patwary et al. 1994), concerns are often expressed about the confidence with which RAPD data can be accepted due to the difficulties in reproducibility of banding patterns in such low stringency PCR with relatively short primers. However, in this case, only bands, which were reproducible (in initial duplicate samples from a few individuals) were scored and the data were recorded as phenotypes (presence or absence of bands) rather than as allele frequencies (which requires the assumption of Hardy–Weinberg equilibrium at a locus).

Two populations of *P. maximus* along the Norwegian coast showed negligible genetic differentiation at Wilding et al.'s (1997) *Pma1* mtDNA marker (Ridgeway and Dahle 2000). However, there was a significant difference between the pooled haplotype frequencies of the two Norway populations and the combined haplotype frequencies of all the populations studied by Wilding et al. (1997) which included samples from the UK, France and Ireland. Direct comparison with those from Scotland to the closest Norway populations was not made.

In conclusion, there is little evidence of substantial genetic differentiation of *P. maximus* populations throughout its range. Apart from the possible differences of the Norwegian populations, the only population, which appears to be genetically isolated from others is Mulroy Bay. Because of the enclosed nature of Mulroy Bay, self-recruitment of the scallop population is probably the rule. Isolated in this way for around 10,000 years since the last Ice Age, the forces of random genetic drift and natural selection for local adaptation can readily explain the genetic differences observed. This genetic isolation may have important consequences for aquaculture of *P. maximus*. Mulroy Bay has been a regular source of scallop spat for aquaculture enterprises elsewhere although the genetic integrity of the Mulroy Bay scallops has probably not yet been compromised by the transfer of scallops into the Bay from other sites (Beaumont 2000b).

10.3.3.4 *Aequipecten opercularis*

Mathers (1975) investigated variation at the glucose phosphate isomerase (*Gpi*) locus in populations of *A. opercularis* and the black scallop *M. (Chlamys) varia*. He showed that *Gpi* allele frequencies differed significantly between populations of *A. opercularis* on the West and on the East coasts of Ireland. In a more extensive study, Beaumont (1982a) proposed at least four relatively genetically isolated regions of *A. opercularis* around the British Isles, namely (a) the North and West Scottish coast, (b) the Irish Sea, (c) the West Brittany and West Irish coast and (d) the English Channel. These conclusions were based

on data from 3 enzyme loci (leucine amino peptidase (*Lap*), phosphoglucosmutase (*Pgm*) and *Odh*) and one non-enzymatic protein locus (*Pt-A*, Beaumont and Gruffydd 1975) but the enzyme loci contributed little towards population differentiation. The most striking geographical differences were in the frequencies of the three *Pt-A* alleles: *Pt-A*³ was most frequent in the Irish Sea and some English Channel populations, *Pt-A*² was commonest in the North and high frequency of *Pt-A*¹ characterised populations on the West coast of France and Ireland (Beaumont 1982a). Mean values of Nei's (1978) *D* for pairwise comparisons between these regions range from 0.178 to 0.233, while values within regions are generally less than 0.02. Allowing for the fact that the *A. opercularis* genetic distance values are derived from only three loci, and that it is only the *Pt-A* locus which shows big differences in allele frequency, the data nevertheless do suggest that the samples come from distinct populations within a single species.

Almost all the *A. opercularis* samples from all populations were in good agreement with Hardy-Weinberg expectations which reduces the likelihood that strong genotype dependent selection is changing allele frequencies each generation and the conclusion was therefore drawn that restricted gene flow caused the observed population differentiation. Data on currents, to some extent, support this conclusion but no similar population differentiation was evident in *P. maximus* (Beaumont et al. 1993; Wilding et al. 1998), which is surprising given the similarity of their distributions, their larval longevity and dispersal capacity (Beaumont and Barnes 1992).

Neither Beaumont (1982a) nor Macleod et al. (1985) were able to detect significant genetic differentiation amongst *A. opercularis* stocks within the Irish Sea although the latter authors did show that the source of recruitment of some Manx stocks may differ from year to year. Lewis and Thorpe (1994a, 1994b) explored this observation further by analysis of 4 allozyme loci in 12 UK populations each of which were sub-divided into year classes based on shell ring counts. They were unable to detect any significant allele frequency differences between year classes within any population, but did demonstrate significant geographic differentiation between some of the populations. However, because Lewis and Thorpe (1994a) used a discriminant function method to analyse their allele frequency data, neither *F* statistics, nor genetic distance values are provided which makes it difficult to relate their results to other studies.

10.3.3.5 *Chlamys islandica*

Fevolden (1989, 1992) analysed genetic differentiation in populations of *C. islandica* from Anddamen (Norway), Møffen (Spitzbergen), Jan Mayen Island and Bear Island using 6 polymorphic loci. Values of Nei's *D* ranged from 0.005 to 0.02 with the greatest genetic separation evident between the Norwegian mainland sites (Anddamen and Tromsø) and all other sites (Fevolden 1992). Fevolden (1992) discusses the various mechanisms, which might be active in maintaining these minor genetic differences between populations and concludes that both adaptive selection and genetic drift may contribute to the observed population differentiation.

There is a small North American fishery for *C. islandica* as well as the major fishery for *P. magellanicus*. One management tool of the fishery is to set the minimum number

of meats per 500 g and this has worked well for the *P. magellanicus* fishery. However, *C. islandica* has a smaller meat at commercial size than *P. magellanicus* and, the scallops are shucked at sea, and the meats are impossible to separate visually. This leaves open the opportunity for vessels supposedly working the *C. islandica* fishery to land large numbers of meats from undersize *P. magellanicus*. Kenchington et al. (1993) identified diagnostic allozyme differences and specific 18S rRNA gene RFLP differences, which enable unequivocal genetic identification of muscle tissue from the two species and provides a very valuable management tool.

10.3.3.6 *Chlamys farreri*

Zhang and Zhang (1997) examined differentiation at a number of variable allozyme loci between 5 *C. farreri* populations from China. The sample from Haiyangdao (Liaoning Province) differed most from all others with a mean value of Nei's (1978) *D* of 0.068, and this is consistent with the separation of this population from the others by a low salinity coastal current. More recent studies based at the University of Qingdao, China, have used AFLPs to demonstrate the reduction of genetic variation in 2 selected populations of *C. farreri* compared with a wild population (Z. Yu, pers. comm.).

10.3.3.7 *Mimachlamys varia*

In an experiment where samples of *M. varia* were reciprocally transplanted between sites on the West and South coasts of Ireland, Gosling and Burnell (1988) demonstrated significant genetic differences between sites. However, some of these differences were reduced by selective mortalities in transplanted animals and they proposed that both genetic drift and selection were important in maintaining allele frequency differences between sites.

10.3.3.8 *Euvola (Pecten) ziczac*

Samples from the southern and northern extremes of the fishery for *E. ziczac* along the Brazilian coast were analysed at 2 polymorphic loci and revealed alleles unique to each extreme (Wanguemert et al. 2000). Although a wider study is clearly needed, this initial investigation does suggest that there is population differentiation of significance to the fishery for this species.

10.3.3.9 *Argopecten gibbus*

The calico scallop *A. gibbus* occurs on the East coast of the USA, from North Carolina down to Florida, and in the Gulf of Mexico and samples taken from these three regions were investigated by Krause et al. (1994) to test for population differentiation. They used morphological traits (shell shape characters) and allozymes (7 polymorphic loci) but revealed relatively low levels of morphological and genetical differences between the samples. Nei's (1978) *D* was smallest between the two Atlantic coast

populations ($D = 0.009$) and greatest across the Florida peninsula ($D = 0.070$) indicating at least some genetic differentiation. In contrast, Blake and Graves (1995) found insignificant mtDNA restriction site differences between Atlantic and Gulf coast populations of the calico scallop.

10.3.3.10 *The Argopecten irradians species complex*

Strong population sub-structure of *A. irradians*, based on morphological differences between populations on the east coast of the USA, was noted and quantified in the 1960s. The species was classified by Clarke (1965) and Waller (1969), based on morphological data, into three sub-species: *A. irradians irradians* (northern bay scallop - from Massachusetts to New Jersey), *A. irradians concentricus* (Atlantic bay scallop - from New Jersey to South Carolina, and along the Gulf coast of Florida) and *A. irradians amplicostatus* (to the west of Galveston, Texas along the Gulf coast). Furthermore, strong shell size differences in scallops from the Florida bay and Florida Keys area, encouraged Petuch (1987) to propose an additional, very localised, sub-species, *A. irradians taylorae*. Kraeuter et al. (1984) demonstrated that hybridisation was possible between *A. i. amplicostatus* and *A. i. concentricus* and that hybrids had intermediate rib numbers to those diagnostic of the parental sub-species.

Using morphological and allozyme data (Marelli et al. 1997a, 1997b) and mtDNA (RFLP) data (Blake and Graves 1995), Petuch's (1987) claim for sub-specific status of *A. irradians taylorae* has now been effectively dismissed. In addition, these studies agree that samples of North Carolina bay scallops differ more strongly from Florida scallops (supposedly the same sub-species) than they do from samples from Massachusetts (classified as a separate sub-species). Wilbur and Gaffney (1997) collected bay scallops from four regions — the North Atlantic, the East Atlantic, the Gulf coast of Florida and of Texas — and spawned each group and reared the offspring in a common environment. They measured and compared shell parameters between the parental and the offspring groups and concluded that the morphological differences between all four source groups of bay scallops had a genetic basis. Therefore, their results would suggest that the northern *A. a. irradians* and the southern *A. a. amplicostatus* are probably safe distinct groups, but the sub-species *A. a. concentricus* is split into two geographically distinct, and probably genetically distinct groups, one on the East Atlantic and the other from the tip of the Florida Cape round into the Gulf of Mexico. Marelli et al. (1997b) reported a Nei's (1978) D value of around 0.14 between the Florida bay scallops and those from the east coast of the USA. A much smaller D value, around 0.06, separated putative *A. a. irradians* and *A. a. concentricus* populations. While the sub-structuring of the *A. irradians* species complex is becoming clearer, the precise classification of the groups still remains to be resolved. Adamkewicz and Castagna (1998) published evidence for genetic control of shell colour and pattern in *A. irradians*, but whether this will be of value in determining systematic relations between the sub-species is not known.

There is an added complication. According to Rhodes (1991), because bay scallops are an important fishery and aquaculture resource, there has almost certainly been extensive unrecorded mixing of populations of the two Atlantic coast sub-species,

A. a. irradians and *A. a. concentricus*. There is no apparent barrier to hybridisation between the sub-species (Kraeuter et al. 1984) and any hybridisations within mixed populations will make it increasingly difficult to establish the true original taxonomic status of the *A. irradians* complex. The recent development of two very variable mtDNA sequence markers (471 bp and 450 bp) by Seyoum et al. (2003), designed to identify the contribution of hatchery-produced *A. irradians* in the natural populations on the Florida coast, provides an extremely sensitive method for investigation of the wider systematics of this sub-species group.

Samples of a mixed stock of *A. irradians* sub-spp. were introduced into China from the USA during the 1980s and 1990s and these introductions have since resulted in very extensive cultured production of bay scallops (Beaumont 2000b). Blake et al. (1997) investigated mtDNA variation between the original stocks and the Chinese scallops and discovered very significant differences. The potential genetic consequences of introductions such as these are discussed by Beaumont (2000b).

10.3.4 Genetic Differences at Species Level and above

There have been several studies on relationships at the species or genus level based on allozyme data in oysters (e.g., Buroker 1979a, 1979b; Buroker et al. 1983) and mussels (McDonald et al. 1991) but few such studies have been carried out in pectinids. Based on allozyme data, L. Woodburn (in Beaumont and Mason 1987) proposed that the Australian *Pecten* 'species' *P. fumatus* (New South Wales), *P. albus* (South Australia and Victoria), *P. meridionalis* (Tasmania) and possibly also *P. modestus* (Western Australia) should be considered as populations of a single species rather than as separate species. Beaumont (1991a) used allozyme data to investigate the systematic relationships between *P. maximus* and three species, which had previously been placed in the genus *Chlamys*. Pairwise genetic distances (*D*) between all these species ranged from 1.53 to 2.75 (mean 1.99) which is outside the range for species differences within a genus (0.118–1.273) suggested by Ferguson (1980). These data added strong support to the decision of Waller (1991) to place *Chlamys opercularis* into the genus *Aequipecten* and *Chlamys varia* into the genus *Mimachlamys*.

In more recent years, sequence data from mitochondrial and nuclear genes have been used as systematic tools. Pectinid phylogeny has been investigated principally using sequence data from the 18S rRNA gene (Rice et al. 1993; Kenchington et al. 1994; Kenchington and Roddick 1994; Frischer et al. 1999, 2000; Canapa et al. 1999). The distinction proposed by Waller (1991) between the sub-families Pectininae (containing the *Pecten*, *Decatopecten* and *Pallolium* groups) and Chlamydinae (containing the *Chlamys*, *Mimachlamys* and *Aequipecten* groups) is generally supported by these analyses. However, using partial sequence data from another mitochondrial gene, 16S rRNA, Canapa et al. (2000b) concluded that the *Chlamys* group is not monophyletic, implying that not all *Chlamys* spp. can be assigned to a single sub-family. The two *Chlamys* species, which seemed so different were *C. islandica* and *C. glabra*, while *Mimachlamys varia* (which they named *Chlamys varia*) clustered with *C. islandica*. It is worth noting (Table 10.1) that chromosome numbers vary between these species such that *C. islandica*

and *M. varia* both have the modal chromosomal number of $N = 19$, while *C. glabra* has $N = 14$, which is very close to $N = 13$ for *A. opercularis* with which it clusters in Canapa et al.'s (2000b) study. Perhaps some early chromosomal rearrangement was a defining event in the evolution of the pectinids producing two lineages, which would then begin to diverge at both the mitochondrial and nuclear genome. Robertsonian-type chromosomal rearrangements (White 1973) involve changes in centromere position, but are not expected to substantially increase or decrease the amount of chromosomal material. However, the chromosome number differences between *P. maximus* ($N = 19$, the modal number for scallops) and *A. opercularis* ($N = 13$) are reflected in the amount of DNA present in the cell nucleus because the *P. maximus* genome is 27% heavier than that of *A. opercularis* (Rodriguez-Juiz et al. 1996). This suggests that chromosomal changes in the pectinid lineage were not simple Robertsonian events.

Several studies have now questioned the separate specific status of *P. maximus* and *P. jacobaeus*. Allozyme data from Huelvan (1985), incorporated into Beaumont's (1991a) analysis, showed that these two taxa were effectively equivalent to sub-populations of a single species. A further allozyme analysis, supplemented by mtDNA PCR-RFLP, confirmed the very close similarity between them (Wilding et al. 1999). Finally, Canapa et al. (2000a) found only a single nucleotide difference (in 548 bp) in the 16S rRNA gene between the taxa. The ranges of the two taxa overlap, according to Canapa et al. (2000b) an intermediate variety (*P. intermedius*) was once reported, and there is ample evidence that hybridisation between the taxa is possible in the laboratory (Wilding et al. 1999). Although there are morphological distinctions, the consensus is that these two taxa should be regarded as sub-populations of the same species, or possibly as sub-species.

10.3.5 Heterozygote Deficiency

Many allozyme studies on marine bivalves have shown that levels of heterozygosity in populations are often considerably lower than expected under Hardy–Weinberg equilibrium (Zouros and Foltz 1984; Gaffney 1994). Scallops are no exception to this trend and heterozygote deficiencies have been reported at a number of loci in *P. magellanicus* (allozyme loci: Folz and Zouros 1984; Volckaert and Zouros 1989; microsatellite loci: Gjetvaj et al. 1997), *P. yessoensis* (Fujio and Brand 1991), *P. maximus* (Beaumont and Beveridge 1984; Beaumont et al. 1993; Wilding et al. 1998), *P. jacobaeus* (Pena et al. 1995), *A. opercularis* (Beaumont 1982a, 1982b), *C. islandica* (Fevolden 1992), *C. farreri* (Zhang and Zhang 1997), *M. varia* (Beaumont and Beveridge 1984; Gosling and Burnell 1988), *C. distorta* (Beaumont and Beveridge 1984), *A. i. irradians* (Bricelj and Krause 1992), *A. purpuratus* (Galleguillos and Troncoso 1991) and *E. ziczac* (Coronado et al. 1991).

A common pattern exhibited in studies involving several loci and several populations is one where a small proportion of the loci studied show a significant deviation from the Hardy–Weinberg model, and in most such cases, the deviation is towards too few heterozygotes (positive value of Selander's (1970) D , or negative value of F_{is}). The second frequent observation is that significantly more than half of the tests of Hardy–Weinberg equilibrium will have a negative F_{is} (or positive D).

Data from Beaumont et al. (1993) are presented in Table 10.4 to illustrate these characteristics and it can be seen that overall, 61 of the 99 individual test F_{is} values are positive, and 7 of the 8 mean F_{is} values are positive. Both these are significantly different ($p < 0.05$ by Sign Test; Sokal and Rohlf 1991) from the equal numbers of positive and negative predicted by the Hardy–Weinberg model. Furthermore, only one of the 19 tests showing significant values of F_{is} (without Bonferroni correction) is for a negative F_{is} . The pattern differs between loci: in some cases such as *Me-2*, the heterozygote deficiency is very pronounced in all populations, in others, for example *Pgm*, the effect is negligible.

Is such a level of heterozygote deficiency important, and what could be its cause? According to population genetics theory, heterozygote deficiency may appear in the population as a consequence of various processes. One obvious explanation is that heterozygotes may suffer higher mortality at an early stage of the life cycle, so that when the population is sampled after selective mortality has occurred there are fewer heterozygotes than expected. However, several other processes not involving selection may act on the population and cause heterozygote deficiency. One such process is inbreeding, i.e., when matings among relatives occur at frequencies higher than expected by chance alone. In marine bivalves, this may occur either as a consequence of self-fertilisation or when sperm from a given male more often fertilise eggs from related females.

Several scallop species such as *P. maximus*, *A. irradians* and *A. ventricosus* (= *circularis*) are hermaphroditic and, in hatchery situations, some self-fertilisation is the rule rather than the exception (Beaumont et al. 1982; Wilbur and Gaffney 1991; Ibarra et al. 1995). Whether this is the case in the wild is not known, but occasional instances of significant self-fertilisation in natural populations, particularly involving isolated individuals, must at least be a possibility. Perhaps of more relevance is the observation that self-fertilised *P. maximus* or *A. ventricosus* (= *circularis*) larvae do not grow as rapidly as cross-fertilised ones and are therefore less likely to survive to adulthood (Beaumont and Budd 1983; Ibarra et al. 1995).

Although rare hermaphroditic specimens of *P. magellanicus* have been reported (Naidu 1970), self-fertilisation is also an unlikely explanation of heterozygote deficiency in this species because of the rarity of hermaphrodites and the lack of a consistent trend toward heterozygote deficiency at all loci. Excessive fertilisations among relatives could occur only if the spatial distribution of adults is such that close relatives settle next to each other. It is difficult to see how this can happen given that scallops have a planktonic larval stage that experiences wide dispersal. Nevertheless, very interesting evidence is emerging that cohorts of *P. magellanicus* larvae may be able to position themselves in the water column in a non-random way (Manuel et al. 1996) and this opens up the possibility that related individuals could settle close to each other more frequently than would be expected under truly random dispersal.

If heterozygote deficiencies were being produced by self-fertilisation, or by mating of close relatives, then levels would tend to be similar across loci but this does not appear to be the case in most studies (as illustrated in Table 10.4) thus ruling out self-fertilisation as a major cause of heterozygote deficiency in these species.

Table 10.4

Deficiencies of heterozygotes against Hardy-Weinberg equilibrium at 8 loci in 13 populations of *P. maximus*. N+ve = number of positive Fis values, N-ve = number of negative Fis values, *+ve = number of significant +ve Fis values (without Bonferroni correction), *-ve = number of significant -ve Fis values (without Bonferroni correction). Numbers of tests for some loci do not sum to 13 because these loci were monomorphic in some populations. *Mdh* = malate dehydrogenase, *Me* = Malic enzyme, *Idh* = isocitrate dehydrogenase, *Gdp* = glycerophosphate dehydrogenase. Data modified from Beaumont et al. (1993).

locus	<i>Odh</i>	<i>Mdh-2</i>	<i>Me-1</i>	<i>Me-2</i>	<i>Idh-1</i>	<i>Pgd</i>	<i>Gdp</i>	<i>Pgm</i>	mean totals
Mean Fis	0.078	0.068	0.237	0.288	0.075	0.039	-0.034	0.015	0.096
N+ve	9	7	5	13	6	8	6	7	61
N-ve	4	5	5	0	6	5	7	6	38
* +ve	1	1	5	8	2	1	0	0	18
* -ve	0	0	0	0	0	0	1	0	1

The next hypothesis to be considered is population subdivision and mixture. This hypothesis (also known as the Wahlund effect) assumes that the species exists as a collection of sub-populations and that matings occur randomly within sub-populations, but matings between sub-populations do not occur or are severely restricted. The resulting zygotes may, however, disperse and be mixed so that, upon settlement, the sampled population will not consist of individuals resulting from one but from several random mating pools of individuals. In such cases genotypic frequencies will not be in Hardy-Weinberg proportions, but will exhibit heterozygote deficiencies. The level of heterozygote deficiency produced will depend on the degree of difference in allele frequencies between breeding sub-populations and considerable allele frequency heterogeneity is needed to generate significant deficiencies. Although population subdivision and mixture is an attractive hypothesis it has proven elusive to rigorous test. One consequence of the hypothesis is that it should produce non-random association between non-allelic genes creating two-locus disequilibria (Nei and Li 1973; Li and Nei 1974) but Gaffney (1994) failed to find any evidence of this in data sets from *Crassostrea virginica*, *Mulinia lateralis* and *A. irradians*. Further evidence against this hypothesis is the consistent lack of significant allele frequency heterogeneity in scallop species: there is, in effect, no sub-population structuring.

One source of heterozygote deficiency at allozyme loci could be the existence of one or more null alleles (alleles which code for a non-active protein product). In the case of a locus coding for a monomeric protein (heterozygotes produce 2 bands on the gel) individuals which are heterozygous for a null allele and an active allele will be mis-scored on electrophoretic gels as homozygotes for the active allele producing an apparent deficiency of heterozygotes. At dimeric protein loci (where heterozygotes exhibit 3 bands on the gel) it is theoretically possible to identify null / active allele heterozygotes, but

often individuals exhibiting unexpected banding patterns are excluded from analysis. Because null allele homozygotes are expected to be lethal, null allele frequencies are not likely to be high in natural populations but there may be several such alleles at a locus and their detection is difficult. In pair matings, however, null heterozygote parents can be detected when offspring genotypes are scored. There have been several studies on bivalves which have detected a surprisingly high frequency of null alleles at a number of loci (see review by Gaffney 1994; Hoare and Beaumont 1995; Del Rio-Portilla and Beaumont 2000) and it is therefore probable that some of the heterozygote deficiencies detected in scallops could be the result of mis-scoring of genotypes due to the presence of null alleles.

One interesting observation concerning the heterozygote deficiency in populations of oysters and mussels is that the deficiency is more pronounced in young cohorts and declines as the cohort becomes older (Zouros et al. 1983; Diehl and Koehn 1985). Foltz and Zouros (1984) examined this phenomenon in a large sample of *P. magellanicus*, which had been aged by counting the annual rings on the shell and resilium (Merrill et al. 1966). The mean number of heterozygous loci per individual within each age group was determined by electrophoresis at six loci and this number increased with age. This suggests that heterozygous scallops survived better than homozygous ones and would indicate a reduction in any heterozygote deficiency with age. Fujio and Brand (1991) also found higher heterozygosity in larger *P. yessoensis*. However, contradictory results have been reported for other scallop species. Larger individuals of *P. maximus* were, on average, less heterozygous at the *Gpi* locus than smaller ones (Wilkins 1978). Also, heterozygosity at the protein *Pt-A* locus was lower in larger than in smaller size classes of *A. opercularis*, while significant variation in *Pgm* heterozygosity occurred between year classes rather than simply between size classes (Beaumont 1982b). Fevolden (1992) tested cohorts of *C. islandica*, aged by ring counts, but found no effect of single locus, or multiple locus heterozygosity on longevity.

10.3.6 Heterozygosity and Growth

Growth is a critical trait in marine molluscs because faster growth in the wild translates into higher viability. Larger animals are more likely to escape predators, to survive periods of starvation due to their larger energy reserve, to enter reproductive age earlier and, once mature, to produce larger gonads. From the aquaculture point of view, faster growth is a self evident objective. For these reasons, some of the genetic studies on bivalves have addressed, directly or indirectly, the relationship between allozyme polymorphisms and growth. Bivalves are good models for such studies because they are relatively easy to collect in large numbers, they can be marked and studied in situ, many species can be aged, and certain species are exposed to environmental conditions that may vary markedly on a micro- or macro-geographic scale. In addition, they have indeterminate growth (unlike, for example, insects that undergo metamorphosis and cease to grow as adults) and shell length is a permanent record of growth (it cannot regress with time like, for example, the weight of mammals). It is well documented that shell

dimensions exhibit high variance, even in cohorts of the same age collected from the same site, and much of this variance must have a genetic basis.

The first studies that looked for a relationship between individual growth and allozyme variation in bivalves were on oysters (Zouros et al. 1980; Koehn and Shumway 1982). They were later widened in scope and extended to mussels (Koehn and Gaffney 1984; Gentili and Beaumont 1988), clams, (Koehn et al. 1988; Gaffney 1990) and scallops (Beaumont et al. 1985; Volckaert and Zouros 1989; Fevolden 1992; Pogson and Zouros 1994; Dolganov and Pudovkin 1995; Rios et al. 1996). To test for this relationship, samples of scallops of known age (either a single cohort, or aged by ring counts) are obtained and scored at a number of allozyme loci. Individuals will be heterozygous at none, one, two, etc. of the scored loci and can therefore be classed into groups according to their multi-locus heterozygosity (MLH). Shell size, or data from some other growth parameter, within each of these groups can then be tested against the null hypothesis that there is no relationship between MLH class and the growth parameter measured. Several (although not all) studies on bivalves have proved the null hypothesis incorrect. This is the phenomenon of the MLH - growth correlation, which can be stated as follows: the expected shell length of an individual is larger, the higher is its degree of its allozyme heterozygosity.

The MLH - growth correlation is an interesting observation and has been the subject of several reviews (Mitton and Grant 1984; Zouros and Foltz 1987; Zouros and Pogson 1994; Britten 1996; Mitton 1998). However, the phenomenon is neither general nor predictable and the number of studies that have failed to detect significant correlations are nearly as numerous as those that have reported positive correlations. Nevertheless, there appear to be certain conditions that favour the correlation and others that do not. Firstly, the correlation does not appear to hold among individuals that have been grown in the laboratory, or are the products of single matings or even mass matings in which the vast contribution of gametes come from few individuals (Beaumont 1991b). Secondly, the MLH - growth correlation is more frequently observed in juveniles, but seldom detected in adults. This may be due to the allocation of energy to gonad production, rather than growth, in mature individuals (Rodhouse et al. 1986).

In contrast to oysters and mussels, studies on scallops have generally failed to find any significant MLH - growth correlation. Foltz and Zouros (1984) examined about 750 *P. magellanicus*, aged by ring counts, but no correlation between MLH and shell length was found, within each age class. This negative study does not have the statistical power of the corresponding studies in other bivalves where sample sizes were much larger, the animals were at the juvenile stage, and there were no uncertainties concerning the age of scored specimens. Volckaert and Zouros (1989) later attempted a more exhaustive study of the correlation in *P. magellanicus*. They examined several age cohorts for the same set of loci as Foltz and Zouros (1984) but again, there was no evidence of a significant correlation (either positive or negative) between MLH and shell size. Beaumont et al. (1985) used both hatchery reared single families and wild caught spat of *P. maximus*, on-grown in lantern nets to the juvenile stage. No MLH - growth correlation was detected. It is perhaps not surprising that this study failed to detect an MLH - growth correlation in offspring of single matings but lack of correlation in the wild caught juveniles was

unexpected. Fevolden (1992) tested cohorts of *C. islandica*, aged by ring counts, but found no MLH - growth correlation in any year class. Studies on *A. i. irradians* and *E. ziczac* have also failed to find MLH - growth correlations (Bricelj and Krause 1992; Alfonsi et al. 1995).

Assuming that heterozygosity at the few loci used in these studies cannot realistically reflect the overall genomic heterozygosity of individuals (Mitton 1998), two main hypotheses have been advanced to explain the MLH - growth correlation. One school of thought holds the view that the enzymes recorded by electrophoresis are the casual agents of the correlation, i.e., heterozygosity for these enzymes directly affect growth rate (the "direct involvement hypothesis", Koehn et al. 1988). Another school (the "associative overdominance hypothesis", Zouros et al. 1988) advances the view that the enzyme variants act as mere markers of genetic abnormalities that are responsible for the genetic variation in growth, but which cannot be detected by the electrophoretic assay involved. Such abnormalities may include null alleles (i.e., variants that do not produce active enzymes), chromosomal losses or homozygosity for linked deleterious genes. An individual that is multiply heterozygous for the marker genes will have a much lower chance of carrying one or more of these abnormalities compared to an individual that is multiply homozygous for the marker genes. This can be equated with the effect of inbreeding (Mitton 1998). Thus, the correlation between electrophoretic heterozygosity and growth results more from the fact that there is a correlation between homozygosity for electrophoretic markers and the presence of a hidden genetic defect than from the direct involvement of the scored allozymes in the animal's physiology.

Testing between these two hypotheses has proved difficult: evidence for the direct involvement hypothesis was provided by Koehn et al. (1988) working on *M. lateralis*, while Beaumont et al. (1995) reported evidence for the associative overdominance theory using cohorts of triploid mussels. Scallops have also featured in the search for confirmation of one or other theory. A critical evaluation requires that the test of the competing hypotheses make opposing predictions. One such test is to compare MLH - growth correlations in a sample of organisms using both allozyme loci and neutral loci. If the direct involvement hypothesis is correct, the correlation should be detected for the allozyme loci, but not for the neutral loci. If associative overdominance is the main causal factor, both sets of loci should show correlations. Pogson and Zouros (1994) developed a specific set of cDNA probes to detect single locus RFLP polymorphisms at sites close to transcribed regions of the genome in *P. magellanicus*. Eight of these RFLP loci were scored, together with 9 allozyme (7 enzyme, 2 non-enzymatic protein) loci, in a large sample of 21 month-old scallops, which had been collected as a single cohort of spat. The shell height of each scallop was accurately measured and tests were made between MLH and shell size for all loci, for the enzymatic allozyme loci alone, and for the non-enzymatic and RFLP loci alone. The results supported the direct involvement hypothesis because a significant MLH - growth correlation was found for the enzymatic loci, but not for the neutral loci. Therefore there is conflicting evidence in the literature supporting both hypotheses. Of course, neither theory need be exclusive. Indeed, there is no reason why both causes cannot be operating in the same genome and the prominence of one or other cause may depend to a great extent on which particular allozyme loci are scored.

Whatever the genetic cause of the MLH — growth correlation, the physiological interpretation seems clear. Koehn and Shumway (1982) and Hawkins et al. (1986) have shown that the degree of heterozygosity relates to basal metabolism. The physiological interpretation of the correlation is that the increased level of heterozygosity (either for the scored enzyme loci or for hidden detrimental genes) enables the individual to sustain its basal metabolism with lower expenditures of ATP. Thus, after meeting their catabolic needs (and provided that everything else is equal), heterozygous individuals are left with higher amounts of energy to fuel other functions. It is suggested that the organism should use this energy in whatever function will provide the maximum returns in terms of Darwinian fitness. For sedentary animals such as mussels and oysters, and for as long as the organism is in the juvenile stage, the best investment is growth. In the mature stages of these same organisms, the best investment will be production of larger gonads. This could explain why the MLH — growth correlation is not found as frequently among cohorts of adults as among juveniles (Diehl and Koehn 1985) and why MLH might correlate with gonadal size (Rodhouse et al. 1986). Garton (1984) proposes that in the predatory snail *Thais heamastoma* the higher energetic efficiency of heterozygotes results in higher predatory activity.

These considerations do not directly help us to explain why MLH — growth correlations are not detected in scallops. In those species of scallop which swim, one may be tempted to suggest that active swimming for the purpose of escaping predators will be the expenditure of surplus ATP favoured by natural selection. If this is the case, then one would not expect to find a correlation between shell size and heterozygosity. One would expect, however, to find a correlation between heterozygosity and survival, since the essence of the hypothesis is that heterozygotes, through their enhanced ability for active swimming, escape predation more effectively than homozygotes. The results of Volckaert and Zouros (1989) are consistent with this explanation, but as noted earlier, evidence from other studies does not show differential survival of heterozygotes (Wilkins 1978; Beaumont 1982b).

Volckaert and Zouros (1989) attempted to obtain more direct evidence for the hypothesis that heterozygous scallops may have higher scope for movement. Animals were placed, one at a time, in specially designed chambers and excited by injecting starfish extract in the water with which the chamber was filled. The time to exhaustion was measured and examined in relation to the genotype at the octopine dehydrogenase locus (*Odh*) which is a key enzyme involved in energy metabolism under anaerobic conditions (Beaumont et al. 1980; Gäde 1980). The study revealed that different *Odh* genotypes have different mean times to exhaustion, a relationship, which was not observed at any of the other loci scored. It is possible therefore that the *Odh* locus is under strong selective pressure in the natural environment, most likely because of its importance in the animal's energy availability under stress. If the demands on active and sustained swimming are higher in one population than in another, this may result in one *Odh* allele being favoured in one population and another allele in another population. This could explain why allele frequencies at the *Odh* locus vary among populations more extensively than allele frequencies at other loci (Beaumont and Zouros 1991). If a certain amount of mixture occurs among these populations the Wahlund effect will predict that

the *Odh* locus will also show a higher deficiency of heterozygotes, which was indeed observed. Note, however, that in some cases (e.g., Volckaert et al. 1991) Bonferroni corrections of probabilities question the significance of *Odh* heterozygote deficiencies. In addition, there is mounting evidence that high frequencies of null alleles can be present at the *Odh* locus (as well as other loci) and these could account for observed heterozygote deficiencies (Gaffney 1994; Hoare and Beaumont 1995).

Others have studied the *Odh* locus in scallops in relation to its biochemistry. Alfonsi et al. (1995) reported that MLH at 6 loci in *E. ziczac* was correlated with the maximal activity of the enzymes pyruvate kinase and octopine dehydrogenase from its adductor muscle. These enzymes are involved in the anaerobic metabolism of adductor muscle swimming and therefore impact on the fitness of the animal. Following from this work Perez et al. (2000) demonstrated that *Odh* heterozygotes have a higher K_m for pyruvate and that this would be a fitness advantage during swimming when pyruvate levels are low. Such apparent overdominance is rather different to the situation in *P. magellanicus* reported by Volckaert and Zouros (1989) where differences between populations were proposed to be due to allele specific selection. Indeed, overdominance for *Odh* would be expected to produce the opposite of heterozygote deficiency, a heterozygote excess.

The search for links between single locus allozyme polymorphisms and specific factors upon which natural selection can act has been undertaken with several species (Mitton 1998) and the demonstration of selection for salinity in *M. edulis* involving the *Lap*⁹⁴ allele by Hilbish and Koehn (1985) is one of the few well documented examples. Krause and Bricelj (1995) investigated the relationship between variation at the glucose phosphate isomerase (*Gpi*) locus and reproduction and growth in *A. i. irradians* from Connecticut, USA. They showed that *Gpi* genotype could be linked with up to 15% of the size of a full grown scallop, but that this effect was not heterotic: it was not necessarily heterozygous genotypes which were exclusively scored in larger individuals. Krause (1995) attempted to explore the rates of flux through the biochemical pathway containing GPI but with limited success. Nevertheless, here is another example of a scored locus, or some other locus in linkage disequilibrium with it, which may affect the fitness of scallops and genotypes at this locus therefore have potential for use in marker assisted selection (MAS) in breeding programmes.

10.4 QUANTITATIVE GENETICS

10.4.1 Heritability and Artificial Selection

Quantitative genetics is the study of characteristics or traits of populations, which are influenced by many genes and also by environmental factors. Examples of such traits are size, weight and growth rate and the phenotypic values of such characteristics can generally be measured on a quantitative scale. A quantitative trait for a population can be described by the mean and the variance of the measurements of the trait from a sample of the population. Phenotypic variance can be partitioned most simply into genetic and environmental components such that:

$$V_p = V_g + V_e \quad (8)$$

where, the total phenotypic variance is V_p , the variance due to genetic differences among individuals is V_g and the component of variance due to environmental differences is V_e . The genetic component may be further partitioned into that due to additive (V_a), dominance (V_d) or epistatic effects (V_i) such that:

$$V_g = V_a + V_d + V_i \quad (9)$$

The term for additive genetic variance describes how much of the total phenotypic variation is passed from generation to generation in a predictable way and the ratio of additive variance to the total phenotypic variance is called the “narrow-sense” heritability ($h^2 = V_a / V_p$) while “broad-sense” heritability ($h^2 = V_g / V_p$) estimates the proportion of phenotypic variation due to all genetic effects.

Values of h^2 may theoretically vary from zero, where phenotypic variance is entirely due to environmental effects, to 1.00, where all the variance is due to genetic effects. The higher the heritability, the greater will be the resemblance between parents and offspring and other related individuals and it is this resemblance between related individuals which is used experimentally to estimate heritabilities of important traits. A number of methods can be used such as regression of full-sib means on the mid-parent mean or comparison of full-sibs, half-sibs or parents (dams and sires) and offspring using analysis of covariance. In addition to the experimental estimation of heritability for a trait, a “realised” heritability can be calculated following artificial selection for the trait in the parents, and its assessment in offspring.

Once values of h^2 have been estimated, programmes of selection involving breeding from the best individuals (“mass” or “individual” selection) or from the best families (family selection) can be undertaken in order to improve the mean phenotypic value of the offspring compared to the parents. For full details of methods of analysis, selection programmes and other aspects of quantitative genetics the reader is referred to Falconer (1981) and Kearsley and Pooni (1996).

Until recently there were no published data on heritabilities of any traits in scallops and no artificial selection programmes had been instigated although some quantitative genetic investigations had been carried out on oysters and mussels (Beaumont 1994). The last decade has seen an increase in interest in quantitative genetics and selection programmes for bivalve shellfish (Beaumont 2000a; Ward et al. 2000) and there are now some published data on quantitative genetics in scallops.

Jones et al. (1996) collected growth data from 20 full-sibling families of *P. magellanicus* and estimated broad-sense heritabilities of larval growth ranging from 1.10 (SE $\pm$ 0.17) to 1.24 (SE $\pm$ 0.40). Strictly speaking, h^2 cannot exceed 1.0, but estimates of h^2 are often imprecise and have high standard errors. Jones et al.’s (1996) results suggest that much, if not all of larval growth rate is controlled by genetic factors but being broad-sense h^2 estimates these include genetic variation due to genotypic combinations within loci and interaction between loci, neither of which are amenable to direct artificial selection. In addition, heritability estimates from full-sib families are

subject to maternal effects and, for example, the quantity and quality of lipids present in the eggs will influence the performance of larvae and may inflate estimates of h^2 . In their study Jones et al. (1996) recorded lipid weight egg^{-1} for all the dams used and, as might be expected, detected a relationship between larval performance and lipid content of the eggs at day 4, but not at later larval stages.

Crenshaw et al. (1991) published a realised heritability value of 0.206 for growth rate in *A. irradians concentricus* based on a single generation of selection. Broodstock scallops were chosen on the basis of their growth rate and only those which grew faster than 1 standard deviation from the mean were used as parents in the selected group. Mating between a random selection of scallops from the whole broodstock provided a control population. Following the observation of reduced larval growth in similarly selected groups of the clam *Mercenaria mercenaria* (Heffernan et al. 1991), Heffernan et al. (1992) analysed embryonic viability and larval growth rate of the offspring from the Crenshaw et al. (1991) selection trials. Offspring from selected lines had significantly lower embryonic survival and larval growth rate than controls. This demonstrated that, as for clams, there was a negative larval response following selection for faster juvenile and adult growth. These results question the merits of the normal hatchery practice of artificial selection of the fastest growing larvae. Further support for this view comes from the demonstration that faster growing *Mytilus edulis* larvae are not guaranteed to become rapidly growing juveniles, and also that faster growing larvae are no more heterozygous at allozyme loci than slower growing larvae (Del Rio-Portilla and Beaumont 2000).

Although the genetic basis of the yellow colour morph of the Chilean (= Peruvian) scallop, *A. purpuratus*, has not been determined, this qualitative trait is associated with reduced growth rate (Wolff and Garrido 1991) and therefore will be a useful marker for selection trials; notably, yellow shelled *A. purpuratus* should not be used as broodstock in trials designed to improve growth rate.

10.4.2 Inbreeding and Hybridisation

One technique, which has proved to be of value in animal and plant breeding, is the production of inbred lines, which are homozygous at the majority of their gene loci. Different inbred lines can be produced to ensure homozygosity for different alleles at the various gene loci and crosses between these pure lines produce hybrid offspring, which are heterozygous at many loci and exhibit 'hybrid vigour' or heterosis.

Many scallop species are hermaphroditic and the potential for the rapid production of inbred lines by the use of self-fertilisation is a feature of importance in such species. Repeated selfings over several generations will produce highly inbred lines more quickly than matings between close relatives because the inbreeding coefficient in selfings (up to a maximum of 0.5) is greater than that for matings between sibs (0.25). As indicated earlier, induced gynogenomes may be almost 100% inbred and could provide an even more rapid method for the production of highly inbred lines. Nevertheless, the higher the degree of inbreeding, the greater is the likelihood of producing deleterious homozygous combinations of alleles at more loci, and thus causing inbreeding depression.

An early study investigated possible effects of inbreeding due to self-fertilisation in *P. maximus* (Beaumont and Budd 1983). Eggs from two adult *P. maximus* were crossed or selfed with sperm from the same parent or from other individuals in a 2 x 5 design. Assessments were made of yield, normality and size of first 'D' larvae on the third day after fertilisation, and of larval size after 2 weeks. Genetic variation was evident at all stages with males and females generally having a significant interactive effect. It was demonstrated that selfing did not significantly effect normality, yield or larval size at day 3 but did cause a significant reduction in growth rate of larvae over 2 weeks. The conclusion from this study was that there were no physiological barriers to self-fertilisation in *P. maximus*, but that inbreeding depression was recognisable in larval growth rate after only one generation of selfing.

Ibarra et al. (1995) have demonstrated similar results on larval growth in selfed *A. ventricosus* (= *circularis*). Larvae were produced from three sources: exclusive self-fertilisations, pair matings or mass spawnings. The authors note that because of the occasional simultaneous release of the eggs and sperm in these hermaphrodites, some selfing may have occurred in the pair matings and the mass mating. In spite of this, significant depression of both larval growth and survival was observed in the exclusively selfed larvae compared with the other groups.

Thus, the production of highly homozygous lines as broodstock by the use of self-fertilisation does not look particularly promising. Nevertheless, as hatchery rearing and on-growing techniques improve, selfing may yet become a feasible strategy in scallop broodstock management.

In principle, offspring with hybrid vigour (heterosis) can be produced by crossing individuals from closely related species, sub-species or different populations. Kraeuter et al. (1984) crossed *A. i. amplicostatus* and *A. i. concentricus* from the east coast of the USA and demonstrated that although rib number and shell colour were principally under genetic control, there was no evidence for heterosis in growth rate. They do point out, however, that all the offspring were reared at the temperature appropriate to only one of the sub-species and that growth differences between the two pure lines and the hybrids may have been due to genes controlling temperature adaptation rather than growth rate.

Cruz and Ibarra (1997) reciprocally crossed two populations of *A. ventricosus* (= *circularis*) from either side of the Baja California peninsula, Mexico, and compared hatchery performance of larvae from the crosses and the pure lines. They discovered a clear maternal effect on early larval growth. Larvae from the Bahia Magdalena population (M) and the reciprocal cross produced with those eggs (MC) had a significantly better survival and faster early larval growth rate than any larvae produced from Bahia Concepcion females (C or CM). This early maternal effect, probably due to higher general productivity in Bahia Magdalena, became non-significant after 11 days. By day 17, there was evidence of heterosis because the mean size of the reciprocal cross larvae was greater than the mean size of pure line larvae. However, it was really the poor performance of the Bahia Concepcion larvae which depressed the mean size of the pure line larvae and neither of the reciprocal cross larval groups were significantly better than the Bahia Magdalena pure line larvae.

The catarina scallop larvae produced by Cruz and Ibarra's (1997) experimental cross (M, MC, CM and C) were settled and grown to 1.5 mm in shell length in the hatchery before being placed out in bags at sites in Bahia Magdalena and Bahia Concepcion (Cruz et al. 1998). As the scallops grew they were transferred from suspended bags to suspended trays and finally to bottom anchored trays. Data on growth and mortality were tested for the effect of age, environment, genetic group and their interactions using analysis of variance. Growth and survival of all genetic groups was significantly lower in Bahia Concepcion, a high temperature, low food environment, than in Bahia Magdalena where temperatures are lower and productivity is higher. Only for one growth character (shell width) was the native population the best population in that environment. No overall significant heterosis of any trait was evident in the reciprocal crosses (MC, CM) over the pure line crosses (M, C). In fact, heterosis was negative for survival and the conclusion of the authors was that the Bahia Concepcion catarina scallops were adapted to their (more stressful) environment and that these adaptations were not present in the Bahia Magdalena scallops.

The poor growth potential of the Bahia Concepcion environment was reinforced by the discovery that none of the scallops in this environment had reached sexual maturity by 7 months (Cruz et al. 2000). In contrast, in Bahia Magdalena, the M and pooled MC - CM populations had a significantly higher gonad index and matured at 4 months compared with the C group, which matured at 5 months. This suggests that there is some genetic element to the control of time of maturation and that this element is dominant because its effect is seen in both reciprocal crosses. This study on catarina scallops by Ibarra's group (Cruz and Ibarra 1997; Cruz et al. 1998; Cruz et al. 2000) is an important demonstration of the need to be wary of population transfers, often warned of by geneticists (e.g., Beaumont 2000b), but seldom tested so clearly in scallops.

Studies on inbreeding effects and heterosis in oysters have produced conflicting results (Lannan 1980; Longwell and Stiles 1973; Mallet and Haley 1983; Hedgecock et al. 1995, 1996; Bierne et al. 1998). Some authors report reduced larval viability due to inbreeding but others, while demonstrating increased growth rate in outbred offspring have shown an increased larval survival in inbred offspring. In trials with *C. gigas*, Hedgecock et al. (1995) demonstrated both positive and negative heterosis in larval and juvenile traits, which were later confirmed by physiological measurements (Hedgecock et al. 1996). Further research is required before the advantages and disadvantages of inbreeding and hybridisation as strategies in bivalve hatcheries can be fully assessed.

10.5 GENOME MAPPING AND GENE SEQUENCES

There are very few published data on genome mapping or linkage groups in bivalves (Foltz 1986; Beaumont 1994; McGoldrick and Hedgecock 1997; Ward et al. 2000) but this aspect of genetics in aquaculture is likely to increase in importance. The use of highly variable markers like microsatellite loci (Gjetvaj et al. 1997), and the ability to rapidly screen large numbers of amplified fragment polymorphism (AFLP) loci for use as genetic markers enables a number of approaches. Linkage of such markers to growth rate or disease resistance can be explored and their relative positions on the chromosomes can

be used to develop a genome map of the species. Such information, together with estimated or realised heritabilities (h^2) for important traits, can be used to design and initiate selective breeding programmes based on marker assisted selection (MAS) and the use of family, individual or mixed family/individual selection (Beaumont and Hoare 2003).

There are an increasing number of publications reporting sequences of specific genes or chromosomal regions in scallops. Examples include an actin gene in *P. magellanicus* (Patwary et al. 1996), telomeric DNA in *A. irradians* (Estabrooks 1999), *Adamussium colbecki* satellite DNA with homology to the mammalian CENP-B box (Canapa et al. 2000a), ribosomal internal transcribed spacers (ITS) in *C. farreri* (Y. Yu, pers. comm.), the troponin C and calcineurin genes in *P. yessoensis* (Yuasa et al. 2000; Uryu et al. 2000), histone gene in *P. magellanicus* and *A. irradians* (Brown et al. 2000), expressed sequence tags (ESTs) and the metallothionein gene in *A. irradians* (Picozza et al. 2000), the scallop ATPase molecule (Ryan et al. 2000) and the fructose-1,6-biphosphate aldolase gene in *P. magellanicus* (Patwary et al. 2002). Such information, although mainly of a descriptive nature at present, is of great potential importance in the understanding of the genome of scallops and in the emerging technology of gene transfer and the production of genetically modified organisms (GMOs) (Cadoret et al. 2000; Hackett and Alvarez 2000; Moav 2000; Powers and Kirby 2000).

10.6 CONCLUSION

Genetic studies on scallops have helped to advance knowledge in a number of areas of scallop biology notably, stock structure, taxonomy, evolution, fisheries and aquaculture. The main focus of studies using allozymes and more recently developed DNA markers has been on the search for population differentiation, species level differences and higher level systematics. The identification of genetically distinct populations such as the Mulroy Bay *P. maximus* population, and the differentiation of Russian and Japanese populations of *P. yessoensis* are of fundamental value to the fishery for these species, and their management for aquaculture. Studies on chromosome numbers and karyotypes have provided data for many scallop species, which are relevant to their taxonomy and these more traditional approaches have been supplemented by the use of sequence data from rRNA genes. It is clear that the classification of scallops, and ideas about their evolution based on paleontological studies have been strongly influenced by these new data. Continuing discrepancies between various approaches illustrated in this chapter show that there is more of the story still to be told.

The contribution of studies on scallops to the phenomena of the MLH - growth correlation and heterozygote deficiency has been important and scallops have been used as experimental organisms to elucidate the possible causes of these phenomena. In addition, studies on the relationship between heterozygosity and metabolic parameters such as growth and viability are of increasing relevance to the aquaculture of scallops as well as other bivalves. Other areas of scallop genetics, such as the use of selfing to produce inbred lines, the production of triploids, and the estimation of heritabilities of

quantitative traits are all fields of research, which could make important contributions towards scallop aquaculture.

As hatchery production of scallops takes on increasing importance, developments currently emerging in the domestication of oysters will be, or are already being employed to enhance scallop aquaculture. Examples include the development of genome maps with linkages to quantitative trait loci (Ward et al. 2000) and, assuming that ethical issues surrounding GMOs can be satisfactorily resolved, the use of gene transfer technology (Cadoret et al. 2000; Lin et al. 2000) to enhance performance and develop commercial strains of scallops.

ACKNOWLEDGMENTS

My thanks are due to the many scientists who have attended Pectinid Workshops over the years, who contributed to my understanding of genetics and scallops, and who often allowed me access to unpublished data. My particular thanks are due to Dr. Ziniu Yu and Dr. Zhaoping Wang for their help in accessing work being carried out in China.

Chapter 11

Diseases and Parasites of Scallops

Sharon E. McGladdery, Susan M. Bower and Rodman G. Getchell

11.1 INTRODUCTION

Much has changed with respect to the knowledge of diseases and parasites of scallops since the first edition of this book (Getchell 1991). Many observations made in that review, however, set the stage for the advancements in knowledge described in the present review. Significant progress has been made in diagnostic capability, experience and the ability to distinguish between infectious pathogens and cryptic histopathological lesions in scallops. This has paralleled significant advances in understanding of scallop physiology and behaviour (as described in detail elsewhere in this volume), both under wild and culture conditions. Evidence of this is the progress made in combating opportunistic infections of larvae and juveniles of several scallop species reared under hatchery conditions. Last, but not least, there has been a massive expansion in the diversification of scallop species being brought into stock enhancement and aquaculture programs on a global scale. Parallel development of remote underwater photography technology, for surveillance and stock assessment purposes, as well as, suspension culture techniques, have also greatly improved our capability to detect health challenges in many scallop species - challenges which previously evaded direct observation in the scallop's benthic domain.

The present review will follow that of Getchell (1991), dividing sections by taxonomic group of pathogen. However, a listing by scallop species has also been compiled in Table 11.1, to facilitate scallop specific cross-referencing. The infectious agents described in detail by Getchell (1991) remain, to ensure as comprehensive a reference as possible.

11.2 MICROBIAL DISEASES

11.2.1 Viruses

Only two viral observations from scallops have been reported to date. The first was a salmonid pathogen, Infectious Pancreatic Necrosis Virus (IPNV). This unenveloped, double-strand RNA Birnavirus was found in the King scallop (Coquille St.-Jacques) *Pecten maximus* (Mortensen 1993a; Mortensen et al. 1992, 1998) from Norway. The IPNV particles were isolated from hepatopancreas, gonad, kidney, mantle, gill, rectum and haemolymph preparations of scallops within 24-h of exposure to bath challenges (Mortensen et al. 1992). The virus could still be detected in the hepatopancreas 50 days

Table 11.1

Diseases and parasites of scallops.

Scallop Species	Parasite or Disease	Effect on Scallop	References
<i>Adamussium colbecki</i>	<i>Cibicides refulgens</i> (Foraminifera)	Normally superficial fouling, but penetration of shell can lead to feeding on mantle fluids and scallop weakening	Alexander & DeLaca 1987
<i>Aequipecten (Chlamys) opercularis</i>	Rickettsial-like organism (Bacteria)	None reported	LeGall et al. 1992
"	Unidentified microsporidian (Protista)	No adverse effects observed, under natural conditions	Lohrmann et al. 1999, 2000b
"	<i>Licnophora auerbachii</i> (Protista)	Histological damage to the eyes	Harry 1980
"	<i>Paranthessius pectinis</i> (Copepoda, Crustacea)	None reported	Reddiah & Williamson 1958
"	<i>Modiolicola inermis</i> (Copepoda, Crustacea)	None reported - common in mantle cavity	Reddiah & Williamson 1958
"	<i>Cibicides lobatulus</i> (Foraminifera)	None reported	Howard & Haynes 1976
"	<i>Suberites ficus</i> ssp. <i>rubrus</i> (Porifera)	None reported - associated with reduced fouling by other colonies	Armstrong et al. 1999
<i>Amusium balloti</i>	<i>Sulcascaris sulcata</i> (Nematoda)	Associated with brown lesions in adductor muscle	Cannon 1978; Lester et al. 1980
<i>Amusium pleuronectes</i>	<i>Pinnotheres</i> sp. (Crustacea)	None	Llana 1979
<i>Argopecten gibbus</i>	<i>Marteilia</i> sp. (Ascetosporea, Protista)	Associated with extreme mortalities in SE USA	Moyer et al. 1993, 1995
"	<i>Echeneibothrium</i> sp. (Cestoda)	Associated with gonad atrophy	Singhas et al. 1993
"	<i>Sulcascaris sulcata</i> (Nematoda)	None reported - associated primarily with the gonad	Lichtenfels et al. 1978, 1980; Blake et al. 1984
"	<i>Porrocaecum pecten</i> (Nematoda)	Brown discolouration of the adductor muscle (associated with haplosporidian hyperparasite of the encysted nematode)	Cheng 1967, 1973, 1978; McLean 1983
"	<i>Ceratonereis tridentata</i> (Polychaeta)	Pest	Wells and Wells 1962

Argopecten irradians	”	<i>Tumidotheres (Pinnotheres) maculatus</i> (Crustacea)	Mechanical compression of soft-tissues (gills, mantle, gonad)	Getchell 1991
	”	<i>Odostomium seminuda</i> (Pyramidellidae: Gastropoda)	Mantle retraction	Wells and Wells 1961
	”	<i>Vibrio natriegens</i> (Vibrionaceae, Bacteria)	Associated with mass mortalities in adult scallops at a hatchery in China	Zhang et al. 1998
	”	Chlamydia-like organisms (Rickettsiales, Bacteria)	Mass mortalities of larvae associated with infections in US hatchery. later, suggesting possible sequestering of the viral particles in this organ. Titres dropped below detectable levels after day 8 in the haemolymph and day 30 from the rectum. No evidence of viral replication or pathological effects was found in the scallop tissues, however, it is believed that these scallops may play a significant role as reservoirs of viable IPNV in the natural environment (Mortensen et al. 1992). Other challenges using an Orthomyxovirus-like (enveloped single-strand RNA) virus, responsible for Infectious Salmon Anaemia (ISA) showed no evidence of uptake or carriage by the same scallop species (Bjoershol et al. 1999).

The other observation of "virus-like particles" was reported from the New Zealand scallop *Pecten novaezelandiae*, and was associated with mortalities of up to 39% (Hine and Wesley 1997). The toheroa clam *Paphies ventricosum*, from independent mortalities, was found to carry similar viral-like particles. Light microscopy of diseased scallops revealed necrotic digestive gland epithelial cells, associated with sloughed or pyknotic cells in the tubule lumens. Some sloughed cells contained abnormal granular cytoplasmic inclusions which were DNA-negative. Transmission electron microscopy revealed electron dense, unenveloped virus-like particles (22–30 nm in diameter) in the cytoplasm adjacent to the outer nuclear membrane, or in orderly arrays along the cisternae of highly modified endoplasmic reticulum (ER), of digestive cells. Some cisternae were dilated to form vacuolar inclusions. Secretory cells showed similar viral-like particle arrays with dilated ER but rarely vacuolar inclusions. The ribonucleic acid component, along with the close association with the rough endoplasmic reticulum of infected cells, suggests an enterovirus-like (Picornaviridae) or calicivirus affiliation. However, these characteristics are indicative of a new group of viruses from molluscs, and require more examination in order to determine viral family affinities and their precise role in the mortalities observed.

No other viruses or viral-like particles have been described from scallops to date, although they have been documented from a number of other bivalve species, with increasing frequency, over the last decade (Hine et al. 1992; Comps and Cochenne 1993; Norton et al. 1993; Elston 1997; Hine et al. 1998; Miyazaki et al. 1999; Comps et al. 1999). Many of these more recent investigations have even been successful in determining biochemical characteristics which aid in classification of the viruses under investigation, e.g., the *Herpes*-like viruses of the Pacific oyster *Crassostrea gigas* (Le Deuff and Renault 1999). Viral detection is likely to increase with better access to transmission electron microscopy, however, the persistent lack of self-replicating cell-lines for isolation of marine bivalve (and other invertebrate) viruses continues to hamper investigation of diseases with possible viral aetiology. As noted by Getchell (1991) "*With the imminent development of marine invertebrate cell cultures, the coming decade should be one of rapid expansion of knowledge about viruses of marine animals (Sindermann 1984), including scallops.*" Research into such techniques has been limited, compared to that for finfish and terrestrial cell-lines, thus the need still exists. Until such techniques are developed, scallop (and other aquatic invertebrate) viruses will remain difficult to detect, and many infectious diseases of 'unknown aetiology' will continue to defy accurate diagnosis. Use of finfish cell-lines to isolate viruses from molluscs must also be treated with due caution, since these have been shown to detect pathogens of finfish (and

other contaminants) sequestered by the molluscs, rather than obligate viruses requiring molluscan cells for replication (Hill et al. 1986; Mortensen et al. 1992).

11.2.2 Prokaryota

The most commonly recorded bacterial infections and diseases of scallops are attributed to members of the Gram-negative Vibrionaceae and Rickettsiales (intracellular Rickettsias and Chlamydias). As noted by Getchell (1991), these organisms are not usually harmful to adult scallops, except where bacterial concentrations exceed levels found under natural conditions. This is consistent with the effect of the same and related bacteria on other bivalve species, especially under culture conditions (Elston 1984).

11.2.2.1 Vibrionaceae

Leibovitz et al. (1984) list three bacterial diseases of cultured *Argopecten irradians*: 1) bacterial swarming, 2) bacillary necrosis, and 3) vibriosis. The overwhelming majority of bacteria associated with marine bivalves are Gram-negative. Due to their efficient filtering mechanism, bivalves are able to accumulate large numbers of microorganisms from the surrounding seawater and thus harbour a rich bacterial flora. The role of bacteria as organisms causing disease in bivalves is not always clear. Species of *Pseudomonas* and *Vibrio* (*Listonella* and *Photobacterium*) are natural constituents of the molluscan digestive tract. Yet, species of these genera have been shown to cause most bacterial diseases of affected pelecypods. The pathogenicity of bacteria for bivalves appears to be negatively correlated to age of the mollusc, decreasing as they grow older (Lauckner 1983). Recent studies by Lambert and Nicolas (1998) have clearly demonstrated a direct inhibition of haemocyte chemiluminescent (CL) activity (associated with intracellular degradation of phagocytosed particles) in both *Pecten maximus* and the Pacific oyster, *Crassostrea gigas*, when challenged with several strains of Vibrionaceae and *Alteromonas* spp. Bacterial strains associated with mortalities of oyster larvae produced less CL inhibition in scallop haemocytes than in oysters and visa versa. This is consistent with other observations where bacterial strain and species can be clearly identified and host specificity examined (Nicolas et al. 1996). Although still recognised as principally a larval problem, exceptions are now beginning to emerge for adult bivalves, including scallops (Zhang et al. 1998).

Under hatchery conditions, scallops are most commonly attacked by vibrionaceae at the velar stage of their development. The role of similar infections in wild population dynamics is poorly understood; however, hatchery holding of high concentrations of larvae in flow-through systems, often fed by waters at higher than ambient temperature to accelerate growth and feeding, appear conducive to bacterial “blooms” and subsequent mortality events (Elston 1984). Any physiological stress due to crowding, feed detritus accumulation, rapid water quality changes (pH, oxygen, turbidity, etc.) should, therefore, be regarded as a potential trigger for bacterial proliferation and bacillary necrosis.

Tubiash et al. (1965) determined the pathogenicity of various bacteria by inoculating 24-h suspensions of the test organism into 400-mL cultures of 2 to 7 day old larvae. Host

susceptibility was determined in a similar fashion, with *Argopecten irradians* larvae as well as other bivalves being challenged with an isolated bacterial strain of high virulence. The Gram-negative bacilli were obtained from dead and moribund bivalve larvae. The disease noted was termed "bacillary necrosis".

The course of the disease was swift and dramatic. Early signs, 4 to 5 h after inoculation with the bacterial pathogen, included a reduction of motility and the presence of many larvae lying on the bottom with either their rudimentary foot or velum extended. With this quiescent behaviour came the spreading of 'swarms' of bacteria from separate foci within the culture. By 8 h, death began to appear, with widespread granular necrosis of the tissues. Examination by light microscopy revealed massive invasion by bacteria throughout the larval tissues. In a heavily infected larval culture, mortality often reached 100% within 18 h. Ciliated protists appeared as secondary invaders at the height of the epizootic, possibly feeding on the bacteria. *A. irradians* larvae experienced 100% mortality after 12 h when challenged with Tubiash's pathogen M 17, presumably a species of *Vibrio*.

Guillard (1959) also described the course of bacterial infection of bivalve larval cultures. The mechanism by which the bivalve larvae were destroyed was suggested to be by invasion or at least contact, rather than by a bacterial exotoxin. Tubiash et al. (1965, 1970) concluded that the entry of the pathogen was via the alimentary tract because malformed, non-feeding larvae were the last to show signs of the infection. And finally Brown and Losee (1978) have suggested that bacterial pathogens attach to and penetrate the velum and presumably spread from this site.

More recent examples of hatchery-based vibriosis problems have been described by Di Salvo (1994), Chavez and Riquelme (1994) and Riquelme et al. (1995, 1996, 1997, 2000) in the Chilean scallop, *Argopecten (Chlamys) purpuratus*, from northern Chile. These authors found the predominant bacteria to be *Vibrio anguillarum*-like strains. Challenges with cell-free supernatant prepared from bacterial cultures reduced larval scallop survival indicating a possible endotoxin effect, rather than bacterial penetration of the tissues. Mortalities were most rapid and significant at water temperatures of 25°C. Similar results were found with *Pseudomonas* sp. and *V. anguillarum* infections of larval *Euvola (Pecten) ziczac* scallops from Venezuela (Lodeiros et al. 1989, 1992).

Pecten maximus larvae in scallop hatcheries in France have also suffered mass mortalities due to vibrios. Although vibriosis has been a common feature of *P. maximus* production for over 15 years in Brittany hatcheries, only recently has differentiation and identification of a new species of *Vibrio* (related to the *Vibrio splendidus* group) been possible via immunoassays and nucleic acid sequencing (Nicolas et al. 1996; Lambert and Nicolas 1998; Lambert et al. 1999a). Interestingly, another *V. splendidus* related strain was isolated from brown inner shell deposits in 3-year-old broodstock *P. maximus*, showing signs of debilitating disease. Although challenges with isolates from these shell deposits reproduced the disease, identical isolates from control scallops as well as inlet water precluded determination of the exact cause-effect relationship (Lambert et al. 1999b). Infection by another vibrio, *Vibrio tapetis* is also associated with brown shell deposits and high levels of mortality in the clam species *Tapes decussatus* and *T. philippinarum* in Atlantic Europe (Nicolas et al. 1992; Borrego et al. 1996).

The only other documented case of mortalities of adult scallops attributed to *Vibrio* infection, was a recent report from China, where adult *Argopecten irradians* suffered mass mortalities in a hatchery in Shandong Province in 1996. Bacteria isolated from the kidney of one of the affected scallops was characterised serologically as *Vibrio natriegens* and challenge experiments using this isolate reproduced the clinical signs observed during the initial outbreak, namely digestive tract and kidney haemocyte infiltration, along with gonad and mantle atrophy (Zhang et al. 1998). No other vibrios have been reported as causing disease problems in adult scallops, in culture facilities or under open-water conditions.

11.2.2.2 Intracellular Prokaryotes (Rickettsiales; Chlamydiales and Mycoplasma)

Obligate intracellular parasites, notably the Rickettsiales and Chlamydiales, are commonly found in the epithelial cells of the gills and digestive diverticula of a wide range of bivalves, including scallops (Chang et al. 1980). Most infections appear benign, despite relatively dense colonisation. However, Leibovitz (1989) reported chlamydiosis as a serious disease of larval and postmetamorphic bay scallops, *Argopecten irradians*, in a hatchery and Morrison and Shum (1982) described a chlamydia-like organism from the digestive diverticula of older juveniles and adults of the same species. The presence of reticulate and elementary bodies within the inclusions in infected epithelial cells indicated that the pathogen was more related to the chlamydiales than rickettsiales, since the latter possess a single developmental stage compared with the at least two forms that comprise the chlamydial life-cycle. About 40% of the bay scallops examined were infected, as well as many giant sea scallops, *Placopecten magellanicus* (Morrison and Shum 1982). Basophilic staining (haematoxylin and eosin) spherical, or sub-spherical, inclusion bodies were seen within intracellular vacuoles in the epithelial cells of the blind-ending tubules of the digestive diverticula. The inclusions varied in size and in number. Heavy infections were associated with similar inclusion bodies in the kidney epithelia. Morrison and Shum (1982) suggested that the initial invasion may have occurred by endocytosis of the elementary bodies by the tubule epithelial cells (which are responsible for nutrient absorption and waste disposal via endocytosis and pinocytosis, respectively). Since the infections were sometimes heavy and some degeneration of host cells was present, these authors believed the pathogen should have some deleterious effect on the scallop host, but none was evident. Other bivalves present had a much lower prevalence of infection than either of the two scallop species. A recent investigation of mass mortalities of bay scallops, introduced to Japan for culture purposes, revealed high levels of a similar chlamydial-like infection of the digestive diverticula. This was directly attributed to the mass mortalities by the investigating authors (Wang et al. 1998); however, the precise linkage between infection and pathogenicity remains unclear.

Later work by Morrison and Shum (1983) showed a similar infection in the kidney epithelia of bay scallops (*Argopecten irradians*), which they identified as a rickettsial-like organism, due to the lack of different development stages characteristic of chlamydiales. The kidney rickettsial-like colonies were characterised by separate membrane-bound

vacuoles within the infected cell cytoplasm. The prokaryotes multiplied by binary fission and could expand colony size to a scale that induced hypertrophy of the infected cell.

In 1983, Gulka et al. reported a mass mortality of giant sea scallops, (*Placopecten magellanicus*), in Narragansett Bay, Rhode Island. Gross clinical signs of infection included retracted mantles and greyish, flaccid, adductor muscles, similar to the pathology described by Medcof (1949) which he had associated with ageing scallops and heavy shell infestation by clionid sponges and *Polydora* polychaete worms. In the Gulka et al. (1983) study, however, affected scallops were of varying ages and demonstrated little shell infestation. Histologically there were myodegenerative changes in the adductor muscle and intracellular basophilic inclusion bodies within the epithelial cells of the gill, plicate membrane, and other body surfaces. Heavily infected tissues, especially the gills, often lost normal tissue architecture. Ultrastructural investigation showed that the infectious prokaryote cells possessed a thin cell wall, and measured 1.9–2.9 μm $\times$ 0.5 μm . Uniformity of structure supported tentative assignment to the rickettsial-like intracellular organisms. There was strong correlation between heavy infections and adductor muscle degeneration, described as “gray muscle disease” (Ballou 1984), which the authors postulated was due to gill dysfunction precipitating metabolic stress and pathological changes in the muscle tissue.

In their second examination of this prokaryotic infection, Gulka and Chang (1984) transplanted uninfected *Placopecten magellanicus* to cages in Narragansett Bay. Within 2.5–3.5 months, up to 53% of the transplants became infected. Scallops held in aquaria using the same water were 100% infected after 5 months. Mortality in the caged population was substantially higher than in scallops maintained in the laboratory. Inoculation challenges using homogenates of infected gill tissue resulted in heavy infections of gill tissue within 20–25 days. Attempts to infect the blue mussel, *Mytilus edulis*, and soft-shell clam, *Mya arenaria*, were unsuccessful. Attempts to culture the pathogen also failed, except in gill tissue preparations or via direct inoculation of homogenates into *P. magellanicus*. However, both field and laboratory challenges during this study failed to reveal the adductor muscle degenerative changes associated with the earlier investigation. This weakens the suggested linkage between the rickettsial infections and mortalities of *P. magellanicus* in Narragansett Bay. McGladdery et al. (1993a) also reported intracellular basophilic inclusion bodies in other giant sea scallops, with no apparent clinical effect.

Light to moderate rickettsial-like infections of the gill (Fig. 11.1) have also been found in wild, captive and cultured adult bay (*Argopecten irradians*) and sea scallops (*Placopecten magellanicus*) by Leibovitz et al. (1984). In these cases, no significant mortality was detected and larval and juvenile scallops remained free of infection. The organisms were morphologically similar to the prokaryotes in the gills of *P. magellanicus* in Rhode Island (Gulka et al. 1983) and those found in other molluscs by Comps (1983), but differed from the rickettsial-like organisms described from the kidney of bay scallops by Morrison and Shum (1983).

The apparent lack of disease in some cases of rickettsial-like infections in giant sea scallops, compared with extreme pathogenicity in other cases is a conundrum, which occurs in other pectinids; such as *Aequipecten* (*Chlamys*) *opercularis* (LeGall et al. 1992),

Figure 11.1. Rickettsial-like microcolonies (arrows) in the gill epithelia of *Placopecten magellanicus* (giant sea scallop). Hematoxylin and eosin stain; scale bar = 30 μ m.

Argopecten purpuratus (Lohrmann et al. 2000a, 2002), *Mizuhopecten* (*Patinopecten*) *yessoensis* (Elston 1986; Friedman 1994) and *Pecten maximus* (Comps 1983; LeGall et al. 1988, 1991, 1992; LeGall and Mialhe 1992; Kellner-Cousin et al. 1993). However, McGladdery (1998) noted that similar organisms have been *clearly* linked to pathogenic infections in other molluscan species. An exacerbatory effect under sub-optimal growing conditions, as suggested by some larval mortalities under hatchery conditions, is possible. In addition, distinguishing between species, with no marine invertebrate cell-line to assist in isolation and purification, complicates differentiation between pathogenic and non-pathogenic strains. Recent advances with immuno- and nucleic acid-labeling, however, show great promise for overcoming this diagnostic challenge (LeGall et al. 1992).

The occurrence of an interesting third group of intracellular prokaryotes - the Mycobacteria (formerly known as the Mollicutes) has been speculated in association with a pustule disease affecting Japanese scallops (*Mizuhopecten* (*Patinopecten*) *yessoensis*) on the Pacific coast of Canada (Bower and Meyer 1991, 1994; Bower et al. 1992; Bower, S.M., 1998. Synopsis of infectious diseases and parasites of commercially exploited shellfish: Intracellular bacterial disease of scallops. URL: http://www.pac.dfo-mpo.gc.ca/sci/shelldis/pages/ibdsc_e.htm. Date last revised December 18, 2002). Complaints of pinkish-orange pustules up to 10 mm in diameter in the soft-tissues (including the adductor muscle) and conchiolin lined shell erosions along the edge of the shell were investigated and revealed the presence of intracellular prokaryotes in a few haemocytes within abscess lesions or other foci of haemocyte infiltration (Fig. 11.2).

Figure 11.2. (a) Histological section through a pustule in *Mizuhopecten (Patinopecten) yessoensis* consisting of haemocytes at various stages of necrosis including a haemocyte (M) that appears to be engulfing necrotic tissue and another associated with a colony of intracellular prokaryotes (B). Haematoxylin and eosin stain; scale bar = 15 μ m. (b) Electron micrograph of a pustule showing a healthy haemocyte (N indicates its nucleus) which appears to have engulfed a necrotic haemocyte that is infected with prokaryotes (arrows). Uranyl acetate and lead citrate stain; scale bar = 1 μ m.

Pustule lesions may become encapsulated and necrotic. Under ultrastructural examination, a few infected haemocytes and autophagy of infected haemocytes was detected (Bower, S.M., 1998. Synopsis of infectious diseases and parasites of commercially exploited shellfish: Intracellular bacterial disease of scallops. URL: http://www.pac.dfo-mpo.gc.ca/sci/shelldis/pages/ibdsc_e.htm. Date last revised December 18, 2002). Diagnosis is speculative because intracellular prokaryotes could result from the phagocytosis of bacteria from secondary infections and such bacteria could resemble *Mycobacteria* especially because few infected haemocytes were available for examination. However, the lesions appeared to be aseptic apart from the few haemocytes containing prokaryotic organisms. The lesions occurred in Japanese scallops from six grow out localities experiencing poor growth and mortalities in 1989. The condition appeared to be related to sub-optimal culture practices and has not re-appeared in subsequent years.

11.2.2.3 Other bacterial pathogens of scallops

Another adductor muscle abscess condition, called bacterial abscess disease or brown spot disease, has been reported from giant sea scallop (*Placopecten magellanicus*) from several beds along the Maine and Atlantic Canadian coasts. First observed from Harpswell Sound in 1977, this disease was noted in Muscongus Bay in 1979, Damariscotta River in 1980, and St. Croix River in 1981 (Sherburne and Bean 1986). Scallops examined from the Damariscotta River from 1985–1987 had similar mucoid abscess lesions 1–2 mm in diameter scattered throughout the muscle (Fig. 11.3).

Figure 11.3. (a) *Placopecten magellanicus* (giant sea scallop) adductor muscle with “brown spot” abscess, x 10; (b) Corresponding histopathology consisting of normal muscle fibres, haemocyte infiltration, and myotome necrosis. Hematoxylin and eosin stain, x 250.

Five to ten per cent of the larger specimens (mean shell height = 124 mm) collected at two sampling stations in the Damariscotta were found to be infected. Gram positive pleomorphic bacteria were consistently observed from the necrotic foci and morphologically similar bacteria were seen in histological sections prepared from infected adductor muscle, gonad, and kidney tissue (Getchell, unpubl. data). Attempts to culture this probable pathogen have failed. Similar observations in scallops collected off southwest Nova Scotia and Cape Breton yielded bacterial cultures containing both Gram-positive, as well as Gram-negative bacterial species (McGladdery et al. 1993a; McGladdery 1998). Secondary infections probably complicated isolation and identification of the primary cause. Similar to the Japanese scallop pustule disease case, there is an apparent correlation to sub-optimal growing conditions that may trigger development of the “brown spot disease” condition in giant sea scallop. Many giant sea scallops showed extensive shell damage by *Polydora* spp. (mainly *P. concharum*) polychaetes and clionid sponges, including perforation of the adductor muscle attachment site. In Maine, many affected scallops came from estuarine beds subject to wide salinity fluctuations that could compromise scallop condition and their ability to remove entrained sediment resulting in irritation of the soft-tissues. Obviously, this condition requires more investigation.

11.2.2.4 Bacterial management under hatchery conditions

Antibiotic preparations may offer a practical short term means of control for bacillary necrosis in cultured scallop larvae, however, such practices are not recommended for flow-through systems or chronic/prophylactic bacterial management. In addition to the fact that scallop larvae may use many bacteria as a nutritional supplement (Samain et al. 1989; Moal et al. 1996), rapid development of resistance to many antibiotics is now well-documented for a number of aquatic bacteria - especially *Vibrio* spp. (Alderman and Barker 1997). Revisions to government approved antibiotic use in seawater facilities has further restricted their application (Robert et al. 1996). In addition, seawater appears to

have properties, which are antagonistic to the efficacy of some antibiotics (Torkildsen et al. 2000). Another way to avoid difficulties with bacillary necrosis is to optimise water quality and maintain vigilant monitoring of influent pipes, algal food sources and tank surfaces. Every hatchery and laboratory has its own unique set of challenges and must establish its own controls, standards, and preventative measures. However, any evidence of reduced feeding should be treated as an alarm for potential bacterial build up in the system. Feeding of non-feeding larvae rapidly provides an ideal nutrient medium for bacterial proliferation, especially under warm water conditions. Brown and Russo (1979) found that a combination of filtration and ultraviolet irradiation of seawater reduced the occurrence of bacterial diseases. Brown (1981) noted, however, that many shellfish hatcheries do not use any disinfection methods and continue to be plagued by intermittent occurrences of bacteria related diseases that often destroy larval cultures around the sixth day of development. Sanitation and quality of food cultures may be more important than sanitation of the larval cultures themselves (Elston 1984); however, as discussed for vibriosis in *Pecten maximus* larvae, recent work on probiotic bacteria (Ruiz-Ponte et al. 1999; Riquelme et al. 2000) also shows promise for controlling bacterial proliferation.

11.3 MYCOTA

Few cases of fungal infection of scallops or other bivalves have been reported despite the ubiquitous distribution of marine fungi. Lauckner (1983) mentions a shell disease where fungi biodegrade bivalve shells and describes mycotic infections in the soft parts of larval and adult pelecypods, but de-emphasises the dangers fungi pose to bivalve health. The Phycomycete, *Sirolopidium zoophthorum* has been reported to attack cultured larvae of several species of bivalves and was implicated in severe epizootic mortalities in cultivated oyster larvae (Davis et al. 1954). Bay scallops (*Argopecten irradians*) at the same hatchery, however, rarely developed epizootic infections. Larvae of all ages were affected, with branched mycelia evident inside the shell. Infection occurs by the release of zoospores from sporangia that protrude from the shell. In a heavy infection, most of the larvae die within 2 to 4 days, but a small percentage may survive. The *S. zoophthorum* zoospores can be cultured on nutrient agar incubated between 20 to 30°C. Septate thalli show branched development (Loosanoff and Davis 1963). In a recent abstract, Martin et al. (1997) outline the continued occurrence of *S. zoophthorum* infections in the soft-tissues of cultured bay scallop larvae, but no further details on the significance of this infection to health or subsequent survival of cultured bay scallops is provided.

Getchell (1991) reported a single case of a fungal infection in the adductor muscle of *Placopecten magellanicus* from the Sheepscot River, Maine. Examination by light microscopy revealed typical fungi with both mycelial growth and clusters of spores within the lesion (Fig. 11.4) (Sherburne 1982). Hyphae with septate walls and apparent budding were purplish-red in colour by PAS staining. Initial work placed the fungus in the genus *Hormodendrum*. While studying another fungus (*Hormoconis resinae* Deuteromycetes) from lesions in American plaice (*Hippoglossoides platessoides*) collected from the Sable-Western Bank complex off the Scotian Shelf of Nova Scotia, Strongman et al. (1997)

Figure 11.4. (a) *Placopecten magellanicus* (giant sea scallop) histological section of adductor muscle. Mycelial growth and clusters of spores are present within the lesion. Normal tissue is on the left side. (b) Same specimen with fungus showing septate walls and apparent budding from several hyphae. Two rounded spores are evident to the left of the hyphae. Hematoxylin and eosin stain.

investigated complaints of greenish black adductor muscle nodules in giant sea scallop meats from the same area. In addition to culturing a *Cladosporium* sp., the authors also isolated a *Penicillium* sp. from the lesions. No further reports of this condition have been recorded. As with “brown spot” and other infections of this nature - collection of samples from fisheries is often complicated by offshore discard of grossly affected adductor muscle “meats”. No similar conditions have been reported from cultured scallops.

11.4 PROTISTA

11.4.1 Sarcomastigophorea (Amoebae and Flagellates)

Several flagellate and amoeboid infections have been reported from a variety of marine bivalve and crustacean species, however, none have been reported to date from scallops. An interesting possible exception is an unidentified protistan, described as “scallop protistan with a ghostly appearance” (SPG, Fig 11.5), which infects Japanese scallop, *Mizuhopecten (Patinopecten) yessoensis* along the Pacific coast of Canada (Bower et al. 1992, 1994). Although not conclusively identified to Phylum, the parasite does demonstrate characteristics typical of the Amoebida, namely translucent cytoplasmic inclusions, pleomorphic body shape, no surface ornamentation or evidence of flagellae/cilia. The mononuclear cells measure 10–15 μm in diameter, and are found within focal haemocyte aggregations located close to the epithelia of the gut, gonad, gill and mantle. Histological lesions are frequently associated with grossly visible ulcerative lesions in the mantle surface, but infections are normally light. The significance of these infections is not clearly understood and further study is complicated by the sporadic occurrence of the infection. A similar looking organism was also observed in *M. yessoensis* broodstock imported into Ireland from Japan (Bower, unpublished data).

Figure 11.5. “SPG” lesions in *Mizuhopecten (Patinopecten) yessoensis* (Japanese or Yesso scallop) adjacent to the epithelium of the intestinal tract containing abnormally vacuolated cells (arrows) surrounded by intense focal haemocyte infiltration (*). Hematoxylin and eosin stain; x 630; scale bar = 10 μm .

11.4.2 Labyrinthomorpha (Thraustochytrids and Labythinuloids)

No labyrinthuloids have been reported from scallops, to date. However, the infectious agent of bay scallops, *Argopecten irradians*, initially described by McGladdery et al. (1991) as *Perkinsus karlssoni* (Fig. 11.6), but subsequently recognised as not being a perkinsiid (Goggin et al. 1996), shows ultrastructural features that may place it closer to the thraustochytrid/ labyrinthuloid complex, than the apicomplexa.

11.4.3 Apicomplexa

Included within the phylum Apicomplexa are three groups of molluscan pathogens that have been identified in scallops, the perkinsiids (Perkinsorida), coccidians (Eucoccidiia) and gregarines (Eugregarinida).

11.4.3.1 Perkinsorida

The first perkinsiid reported from scallops was a *Perkinsus* sp. from *Mizuhopecten* (*Patinopecten*) *yessoensis* imported to the Popov Islands on east coast of Russia from Japan (Kurochkin et al. 1986). The pathological effects of the lesions described were not elucidated and no further reports on this infection have been published.

Another perkinsiid was encountered in the same scallop species cultured in British Columbia, Canada. Initially, the infectious agent was reported as Scallop Protistan Unknown (SPX) (Bower et al. 1990, 1992, 1995, 1997, 1998; Bower and Meyer 1994), however, detailed taxonomic investigation has confirmed SPX as a new species of perkinsiid, *Perkinsus qugwadi* Blackburn, Bower and Meyer, 1998 (Blackburn et al. 1998) (Fig. 11.7). This infection is believed to be native to BC, and is characterised by

Figure 11.6. (a) '*Perkinsus*' *karlssoni* lesions in the connective tissue and stomach epithelium of a pre-spawning *Argopecten irradians* (bay scallop). Hematoxylin and eosin, x 160; (b) High power (x 630) of protistan-like inclusions within lesions and surrounding hyalinocyte response. Hematoxylin and eosin.

Figure 11.7. (a) *Perkinsus qugwadi* trophozoites (arrow) and tomites (*) in connective tissue of *Mizuhopecten* (*Patinopecten*) *yessoensis* (Japanese or Yesso scallop); (b) vacuolated trophozoites ('signet-ring' form) of *Perkinsus qugwadi*; and (c) zoospore stage of *Perkinsus qugwadi* (arrows). Hematoxylin and eosin stain; x 1000 (oil).

massive proliferation throughout the connective tissues of all organs, leading to weakening and death. Infected scallops may demonstrate creamy-white pustules up to 5 mm in diameter in many tissues, especially the gonad, but these appear to bear no direct correlation to level of infection. The disease is not easily transmitted from scallop to scallop, with most transmission being confined to a few heavily infected juvenile scallops (<40 mm shell height) within which zoospores develop (a characteristic, which differs from all other described *Perkinsus* species where sporocyst development is external (Perkins 1996)). Progeny of *M. yessoensis* that survived an epizootic outbreak of *P. qugwadi* had a significant increase in resistance to infection and resulting mortalities. Hybrid scallops, resulting from a cross between *M. yessoensis* females (from the same group of scallops that survived an epizootic outbreak of *P. qugwadi*) and *Patinopecten caurinus* males (native to British Columbia), had similar resistance to *P. qugwadi*. The identification of scallop stocks that are resistant to *P. qugwadi* has facilitated the development of a scallop culture industry in British Columbia. No other native sympatric scallop species (*Chlamys rubida* or *C. hastata*) appear to be susceptible (Bower et al. 1999).

As discussed under Section 11.4.2, the taxonomic status of a bay scallop parasite identified as *Perkinsus karlssoni* by McGladdery et al. (1991), is now recognised to be invalid, based on the morphology of the biflagellate stage isolated from infected scallops by culture in fluid thioglycollate media (Whyte et al. 1993a) and by DNA analysis of cultured isolates (Goggin et al. 1996). Nevertheless, the possibility that the biflagellate isolates analysed to date were not free-living contaminants from scallop tissues but are representatives of the pathogen observed histologically remains to be confirmed. The infection was originally described by Karlsson (1991) from bay scallops in Rhode Island. At about the same time, McGladdery and co-workers were investigating bay scallops introduced for culture purposes into Atlantic Canada (McGladdery et al. 1993b, Whyte et al. 1993b). Due to the bay scallops being an exotic species to Atlantic Canadian waters, there was concern over the potential to introduce new infections into

Canadian bivalve population, thus, these investigations concentrated on host-specificity and transmission potential. Results indicated that the infection is specific to bay scallops (Bower, S.M. and McGladdery, S.E., 1996. Synopsis of infectious diseases and parasites of commercially exploited shellfish: *Perkinsus karlssoni* of scallops. URL: http://www.pac.dfo-mpo.gc.ca/sci/shelldis/pages/perkarsc_e.htm. Date last revised September 18, 1996). The infection is characterised by intense swirl-like haemocyte aggregations, within which the parasite is frequently engulfed and masked (McGladdery et al. 1991). Infections were boosted under warm water (20°C) recirculating holding conditions where the parasites became more evident in proliferative masses which distended the basal membranes of digestive tubule and duct epithelia (Whyte et al. 1993b). During these investigations, another parasite infection was also stimulated - a kidney coccidian, described further under Section 11.4.3.2. Interestingly, the coccidian induced a similar haemocyte encapsulation response to that caused by the *Perkinsus*-like parasite, making it difficult to distinguish the two species in advanced cases (Whyte et al. 1994).

11.4.3.2 *Eucoccidiia*

The first report of a coccidian infection in scallops was that of Léger and Duboscq (1917) who described a new species, *Pseudoklossia pectinis*, from the kidney of European great scallop (King scallop, Coquille St.-Jacques), *Pecten maximus*, from Roscoff, France. Oocysts of this species measured 32 to 35 µm in diameter and were found solely in the kidney epithelial cells, where gamonts were also detected. A recent review by Desser and Bower (1997), however, questions the assignation of this species to the genus *Pseudoklossia* due to the description by Léger and Duboscq (1917) of syzygous division in the gamont stage. Desser and Bower (1997) note that this is a taxonomic feature of the family Adeloridae, rather than the Aggregatidae within which *Pseudoklossia* currently occurs. No meronts (schizonts) were found which is consistent with the belief that most eimeriid coccidians have a heteroxenous life-cycle. Schizogony (merogony) takes place in one host and gametogony and sporogony take place in another host. No further descriptions, reports or investigation of the significance of this parasite to *P. maximus* have been reported.

Leibovitz et al. (1984) were the first to describe heavy renal coccidial infections in captive and cultured adult bay scallops, *Argopecten irradians* (Fig. 11.8). The disease consisted of coccidia at different life stages infecting the epithelium of the kidney, causing tissue destruction within the kidney, and renal tubule impaction by coccidia and epithelial debris. In cultured scallops, mortalities often exceeded 80% and coccidia also occurred in the digestive diverticula, gills, and gonad. Similar infections were also found in wild bay scallops, but less frequently and with limited pathology. Similar observations were subsequently reported from bay scallops held in captivity in Atlantic Canada as part of a host specificity study for an unrelated infection (Whyte et al. 1994). Although more than one type of oocyst was described by Leibovitz et al. (1984), suggesting the possible presence of more than one species, only one coccidian species is suspected in the

Figure 11.8. (a) Extensive proliferation of an unidentified coccidian throughout the renal tubules of *Argopecten irradians* (bay scallop). Hematoxylin and eosin stain, x 160; (b) Meront development and release from epithelial cells of the renal tubule. Hematoxylin and eosin, x 630.

Canadian studies (McGladdery 1990, 1993b; Cawthorn et al. 1992; Whyte et al. 1994), as well as independent eastern US observations (Getchell 1991; Karlsson 1991).

Another coccidian was reported by DiSalvo (1994) from the kidneys of broodstock Chilean scallops, *Argopecten purpuratus*. This was related to production of poor quality gametes, but no further descriptions of the infection have been reported. Other studies of this scallop species have not found this parasite (Lohrmann et al. 1991, 2000a; Lohrmann and Smith 1993) and it is speculated that the infection detected by DiSalvo (1994) may have been opportunistic.

11.4.3.3 Eugregarinida

Most gregarines complete their development within an arthropod host. Members of the family Porosporidae, however, undergo intermediate developmental stages in marine bivalves. Lauckner (1983) summarises the life cycle of these gregarines. At the mid-point in the cycle gymnosporos are drawn into the mantle cavity of a compatible bivalve host where they are engulfed by phagocytes on the surface of the gill or mantle epithelium. It is within these cells that the sporozoites form. The genus *Nematopsis*, which includes most species infecting bivalves, is characterised by the sporozoites being encapsulated by a resistant spore (actually the oocyst stage, according to Lauckner (1983)).

Nematopsis pectinis was identified in *Chlamys (Pecten) varia* from Europe (Léger and Duboscq 1925). Although originally assigned to the genus *Porospora*, Sprague (1970) reviewed the taxonomic description and based on the encapsulation of the sporozoites, transferred them to the genus *Nematopsis*. Their final decapod host was unknown. Similar gregarines have been observed in the Japanese scallop *Mizuhopecten (Patinopecten) yessoensis* and *Pecten (Patinopecten) carinus* (Bower and Meyer pers. comm.). The bay scallop, *Argopecten irradians* has been found to be susceptible to

N. ostrearum, which has an oocyst size of approximately $14 \times 10 \mu\text{m}$ (Sprague 1970). *Nematopsis duorari*, with spores $19 \times 10 \mu\text{m}$, has also been found in *A. irradians*. The final host is the shrimp, *Penaeus duorarum*. Kruse (1966) found that *A. (Aequipecten) irradians* shed *Nematopsis* spores in their mucous strings. These, with other bottom debris, are then ingested by the shrimp. Based on results of infection studies with oysters, Sprague and Orr (1955) decided that the parasites were detrimental to their intermediate hosts, but did not believe that *Nematopsis* was a significant mortality factor in the wild. No pathogenicity has been described for *Nematopsis* infections of scallops.

11.4.4 Microspora

Although microsporidians are obligate intracellular parasites of a wide variety of vertebrate and invertebrate hosts, few bivalves have been found to be infected and only one case in scallops has been reported (Lohrmann et al. 1999, 2000b). The infection was found in *Aequipecten opercularis* (the queen scallop) collected from several sites around the English and Welsh coasts of the UK between 1997 and 1998 (Fig. 11.9). Prevalences ranged from 4.5–20%. Two stages of spore development were observed within the blood

Figure 11.9. (a) Microsporidian colony in the digestive diverticula of *Aequipecten opercularis* (queen scallop) Hematoxylin and eosin, scale bar = $50 \mu\text{m}$. (b) Individual sporocysts within colony, Feulgen stain. (c) Microsporidian colony within digestive gland diverticula, SEM. (d) Individual sporocyst ultrastructure, TEM. (Images kindly provided by Dr. K. Lohrmann, Universidad Católica del Nord, Coquimbo, Chile)

sinuses and tissues of the digestive gland, but no other developmental stages were detected. The authors speculate that other developmental stages may be present in other tissues of the same host, or an alternate host may be involved in the life cycle. Mature spores measured $2.3 \times 1.2 \mu\text{m}$, contained polar bodies with 7–9 coils and were found within the vascular sinuses. Immature spores measuring $2.3 \times 1.2 \mu\text{m}$ were found within hypertrophied host cells (up to $300 \mu\text{m}$ in diameter) in the digestive gland. The polar tube of some spores had 10–12 coils, while others showed only 7–8 coils. There was no overt pathology associated with these infections. Cells infected by immature spores showed only minor focal infiltration and fibroblast like encapsulation layers.

11.4.5 Ascetospora

11.4.5.1 Marteiliida

Several species of *Marteilia* have been well-described from European populations of Flat oysters (*Ostrea edulis*), mussels (*Mytilus edulis*, *M. galloprovincialis*) and a pelecypod, *Scrobicularia piperata*. In addition, the Sydney rock oyster (*Saccostrea commercialis*) and possibly the black-lip oyster (*Crassostrea echinata*) are also host of the marteiliad, *Marteilia sydneyi*. Only one marteiliad has been reported from scallops and its impact was so severe and rapid that no material was available post-epizootic to permit detailed taxonomic investigation. The *Marteilia* sp. was found in mass mortalities of Calico scallop, *Argopecten gibbus*, off the Atlantic coast of Florida in late 1989–90 (Moyer et al. 1993, 1995). The marteiliad overwhelmed the digestive tubules of the scallops, which showed rapid weakening and death. No further infections of calico scallop have been detected since the original reports.

11.4.5.2 Balanosporida

The Balanosporida contain some of the most devastating parasites affecting bivalve molluscs: *Haplosporidium nelsoni* and *Haplosporidium costale*, the causative agents of MSX and SSO disease, respectively, of American oysters (*Crassostrea virginica*); and *Bonamia ostreae* and *Bonamia exitiosus* of European and New Zealand flat oysters (*Ostrea edulis* and *Ostrea lutaria*), respectively (OIE 2003). To date, however, only one unidentified species has been reported from scallops (Chu et al. 1996). More than 83% of bay scallops, *Argopecten irradians* from two stocks being cultured in the Yellow Sea area of China were found infected. Most infections found were light (Fig. 11.10), but heavy post-spawning mortalities in the same area led the authors to suggest that this haplosporidian may be a potential causative factor.

Figure 11.10 (a) Multinucleated schizont stage of an unidentified Haplosporidian parasite infecting the connective tissues of *Argopecten irradians* (bay scallop) collected from China. Hematoxylin and eosin, x 100; (b) and (c) denser plasmodial stages of the same parasite in the mantle and digestive diverticula, respectively. Hematoxylin and eosin, x 250 (images kindly provided by Dr. E.M. Bureson, Virginia Institute of Marine Science, VA, USA).

11.4.6 Ciliates

The majority of ciliates associated with bivalves are, like the flagellates described under Section 11.4.1, probably harmless commensals. More than 150 species of ciliates have been found in the mantle cavity, on the gills, or in the digestive diverticula of marine bivalves. Most are primarily commensal, but can become pathogenic if their numbers become unusually high, the physiological state of the host is compromised, or an environmental stress factor shifts the equilibrium (Lauckner 1983).

Trichodinids are peritrichous ciliates that are common symbionts of amphibians, fishes and bivalves (Fig. 11.11). Most are commensals feeding on bacteria and occurring at low prevalences and intensity of infestation within the mantle cavity. Some infections of trichodinids in bivalves, however, have been linked to tissue damage and mortalities (Lauckner 1983). Trichodinids are easily recognised by their dome shape, rows of cilia, conspicuous circle of hooklets and horse-shoe shaped macronucleus.

In scallops, *Trichodina pecten* has been reported in the mantle cavity of *Mizuhopecten* (*Patinopecten*, *Pecten*) *yessoensis* and *Trichodina polandiae* from *Chlamys* sp. collected from the Gulf of Peter the Great (Sea of Japan) (Stein 1974 cited in Lauckner 1983). The former species is described as having a ring of 22–31 denticles, each denticle having 7–9 radial rods. The species described from *Chlamys* sp. has 20–26 denticles with 7–10 radial rods on each (see Table 13–9 in Lauckner 1983). Another, possibly identical, trichodinid was reported on *M. yessoensis* by Kurochkin et al. 1986. Xu et al. (1995)

reported another species, *Trichodina jadratica* from the gills of *Chlamys farreri*. This ciliate averaged 37.8 μm in diameter with 21–24 denticles and an adoral ciliated membrane spiral of approximately 400°. Lohrmann et al. (2000a, 2002) reported a *Trichodina* sp. from the gills of the Chilean scallop, *Argopecten purpuratus* and trichodinids are also commonly found in the mantle cavity of giant sea scallops (*Placopecten magellanicus*) from Atlantic Canada (Beninger et al. 1988; McGladdery et al. 1993a) (Fig. 11.12). In some *P. magellanicus*, numbers may exceed over 100 per 5 μm thick tissue section of gill, but no tissue damage has been found to date.

Figure 11.12. (a) Unidentified trichodinid ciliates on the surface of giant sea scallop (*Placopecten magellanicus*) from Atlantic Canada. Hematoxylin and eosin; x 160. (b) High power magnification (x 630) of denticle arrangement of one of the giant sea scallop trichodinids. Hematoxylin and eosin stain.

Whilst most trichodinids usually occupy many areas within the mantle cavity of a bivalve, the heterotrich, *Licnophora auerbachii* resides in a more unusual niche, the eyes of the scallop. These ectoparasites are highly motile and very difficult to detach from the eye surface. Harry (1977) found that 85 out of 88 queen scallops, *Aequipecten (Chlamys) opercularis*, collected from County Down, Ireland, harboured *L. auerbachii*. Only a few *Pecten maximus* and *Chlamys varia* were found infested, indicating a degree of host specificity that Harry (1977) was able to confirm with *in vitro* investigations. One specimen of *A. opercularis* was parasitised by ciliates on 94 out of 103 eyes. Loss of pigment from the iris and signs of disintegration were two of the prominent pathological features of this heavily infected individual. Harry (1980) suggested that the action of the basal disk as it attaches caused damage to the epidermis of the eye. Like *Trichodina*, *Licnophora auerbachii* is normally a filter-feeder probably thriving on bacteria (Fig. 11.13).

The eyes of scallops are not able to form focused images, so it is unlikely that the presence of these ciliates affect their visual response to stimuli. However, *L. auerbachii* might have an effect on young developing scallops by interfering with their light-dark shadow detection escape response (Harry 1977, 1980).

11.5 PLATYHELMINTHS

11.5.1 Trematodes

Bucephalid and Fellodistomid digenean trematodes parasitise many species of marine bivalves, and some are known to cause significant damage to the host's reproductive tissue. Sanders and Lester (1981) documented a bucephalid trematode infection of *Pecten alba* from Bass Strait, Australia, which turned the scallops gonad bright red or orange in colour. Histological observations showed the gonads contained sporocysts with cercariae throughout most of the year. The sporocysts occupied the bulk of the gonad as the scallop reached a state of sexual maturation. Over the 6-month period during which sporocysts produced cercariae, the average weight of the adductor muscle fell below that of unparasitised scallops. The loss of reproductive potential and energy reserves stored in the adductor muscle reflect the strain this trematode has on its scallop host. Other *Bucephalus* sp. sporocyst infections of Australian scallops were reported by Heasman et al. (1996). These authors followed infections in two species of scallops (*Chlamys asperima* and *Pecten fumatus*) from New South Wales, Australia, and documented significant increases in prevalence of infection. Over a two year period prevalences increased to 66% in *P. fumatus* over 80 mm in length and 40% in *C. asperima* over 75 mm in length, from 5.1% and 4.3%, respectively in 1991/92.

Mateo et al. (1975) reported castration of *Argopecten purpuratus* from Peru in association with sporocysts showing hemiuiroid characteristics.

Figure 11.13. *Licnophora auerbachii* from the eye of *Chlamys opercularis* showing: 1) oral disc with cilia making up the adoral zone of membranelle (AZM); 2) neck region; and 3) basal disc. (After Harry 1980).

Fellodistomid digeneans belonging to the genus *Proctoeces*, are also well-documented as causing varying degrees of tissue damage in bivalves (Bray 1983). The most commonly reported species is *Proctoeces maculatus*, however, the broad geographic and host ranges reported for this species, have lead some authors to speculate that this name contains more than one species and requires re-investigation (Lauckner 1983; Bower 1995). The metacercarial stage of *P. maculatus* is reported from various Mollusca, Polychaeta and Echinoidea. Adults occur in mollusc-eating fishes such as labrids and sparids, however, progentic development is also documented in mussels, which normally host the sporocyst developmental stage (Bray 1983). Karlsson (1991) described adult worms, tentatively identified as *Proctoeces* sp., from the kidney and opening of the gonoduct into the kidney of bay scallops from Rhode Island. Some trematodes showed attachment to the kidney epithelia via the oral sucker. Although most tissue sections revealed only single worm infections, one scallop kidney section harboured over 50 *Proctoeces*. Bray (1983) also reported *P. maculatus* in bay scallops collected from Rhode Island.

Unidentified metacercariae belonging to the Echinostomatidae, Fellodistomidae or Gymnophallidae have also been reported from bay scallops from Rhode Island. Karlsson (1991) noted varying numbers of metacercariae encysted in the labial palps, digestive gland and gill tissues. Despite numbers exceeding 50 metacercariae per tissue section in some specimens, there was little evidence of a strong host response. Similar metacercariae have been reported from the labial palps of *Argopecten purpuratus* in Chile (Lohrmann et al. 1991), *Chlamys islandica* from the Barents and White Seas (Chubrick 1966, cited in Lauckner 1983), and in *Placopecten magellanicus* from Atlantic Canada (McGladdery et al. 1993a). The echinostomatid *Himasthla quissetensis* uses *Argopecten irradians* as a second intermediate host, before final maturation in the intestine of the herring gull, *Larus argentatus*. The metacercariae, 140–190 μm in diameter, occur in the mantle, gills, and foot, but do not undergo any further development in the cyst (Stunkard

1938). A similar lack of growth occurs when metacercariae of *Renicola thoidus* parasitise *Argopecten irradians*. The adult trematode infects the kidney of shore birds (Getchell 1991). Adult trematodes are rare in scallops and possibly only occur as accidental infections (Fig. 11.14).

In a recent description by Pérez-Urbiola and Martínez-Díaz (2001), a condition known as “pimientilla” disease in catarina scallop *Argopecten ventricosus (circularis)* from Baja California Sur, México, has been found to be caused by *Stephanostomum* sp., a species of Acanthocolpid digenean. This is the first description of this group of digeneans using molluscs as second intermediate hosts. Most other species of *Stephanostomum* encyst in the body cavity of benthic fish and mature in the guts of piscivorous fish. The metacercariae encyst throughout the soft tissues of the scallops, eliciting a strong melanisation response, which gives the scallop a peppery (“pimientilla”) appearance and renders it unmarketable. Except for signs typical for metacercarial infections (i.e., a focal haemocyte infiltration and encapsulation), the effect on the health of the scallop was not reported, despite extremely high levels of infection (Pérez-Urbiola and Martínez-Díaz 2001).

Unidentified larval sanguinicolid have been recorded from *Argopecten irradians* from Woods Hole, Massachusetts (Linton 1915). Interestingly, this group of digeneans develop into adults directly from cercariae, omitting the usual metacercarial encystment stage. Within the bay scallop, the only report of pathology was castration caused by sporocyst proliferation throughout the gonadal tissues. There have been no further reports of sanguinicolid sporocyst infections of bay scallops (or any other scallop) since Linton’s 1915 note, however, Lauckner (1983) provides a thorough review of infections of other molluscan groups.

Figure 11.14. Unidentified digenean embedded in the connective tissue of the digestive gland of *Placopecten magellanicus*. Hematoxylin and eosin stain; x 250. Scale bar = 0.1mm.

11.5.2 Cestodes

Among the helminth parasites of shellfish, cestodes, particularly larval forms (metacestodes), are common inhabitants within the digestive tract of Atlantic bay scallops (*Argopecten irradians*). Seven species of larval cestode were identified in the eastern Gulf of Mexico by Cake (1977, 1979). These include the four most prevalent, *Parachristianella* sp. which encysts singly along the walls of the intestine, *Tylocephalum* sp. in the digestive tract walls and digestive gland, *Rhinebothrium* sp. in the stomach and digestive diverticula, and *Polycephalus* sp. in the visceral masses and digestive gland (Fig. 11.15). The other single isolations were *Acanthobothrium* sp., *Anthobothrium* sp., and *Eutetrarhynchus* sp. *Tylocephalum* sp. metacestodes were also reported from five of 25 *Chlamys nobilis* from Japan (Sakaguchi 1973 cited in Lauckner 1983). The scallops are initially infected by ingesting eggs, gravid proglottids or free swimming coracidia. Because the plerocercoids lack taxonomic characteristics, most larval forms can be identified only to genus.

None of these genera have been associated with overt pathology, most infections being light and eliciting a focal haemocyte response similar to that described for metacercarial digeneans. High levels of infection, however, may cause physiological stress that can affect growth, reproduction as well as edibility. In calico scallops, *Argopecten gibbus*, from North Carolina, high levels of infection by metacestodes belonging to the genus *Echeneibothrium* have been associated with significant gonad atrophy (Singhas et al. 1993). Infections by cestodes of the same genus have also been associated with aberrant behaviour in littleneck clams (*Protothaca staminea* and *P. laciniata*) from California (Sparks and Chew 1966; Warner and Katkansky 1969).

The Chilean scallop, *Argopecten purpuratus* is also known to be infected by larval cestodes. Oliva et al. (1986) found metacestodes, which they tentatively assigned to the Phyllobothriidae and Oncobothriidae, in the gonadal tissues of samples collected from Antofagasta, Chile; and Lohrmann and Smith (1993) found another unidentified larva in the intestine of the same species collected from Coquimbo, Chile. None of the infections was associated with overt pathology.

Because the larval forms infect the viscera of the scallop, which is discarded during processing, there is little chance of humans consuming cestodes with the edible adductor muscle. Any cestodes that are not discarded, however, would be destroyed by the cooking process and Cake (1977) mentions experimental evidence that suggests that *Tylocephalum* larvae are destroyed by human digestive acids and enzymes. The final hosts for all these cestode genera are elasmobranch fish (sharks, skates and rays)

11.5.3 Turbellaria

Turbellarian flatworms are commonly found on the gills or within the guts of a wide range of bivalves (Lauckner 1983), however, few have been reported from scallops. An unidentified turbellarian was reported from the digestive diverticula of bay scallop *Argopecten irradians* (Leibovitz et al. 1984), with no apparent pathological effect.

Figure 11.15. Larval cestodes from the scallop, *Argopecten irradians concentricus*. (a) Encapsulated, acaudate glando-proceroid of *Tylocephalum* sp. (b) Tentaculo-plerocercoid of *Polypocephalus* sp. (c) Bothridio-plerocercoid of *Rhinebothrium* sp. (After Cake 1976).

A turbellarian resembling *Urastoma cyprinae*, a common inhabitant of the gills of American oysters (*Crassostrea virginica*) in Atlantic Canada, has been reported from the gills and body surfaces of giant sea scallop from the same area (McGladdery et al. 1993a) (Fig. 11.16). Compared with oyster infestation levels, those found on the scallops occur in much lower numbers (1–2 per tissue section and maximum prevalences of 10%) than occur on oysters (up to 1000's of *U. cyprinae* and 100% prevalence). In both scallops and oysters from Atlantic Canada, there was no obvious histopathological effect on the gills, however, hypertrophy of gill epithelial cells in mussels from Spain has been attributed to the same turbellarian (Robledo et al. 1994) and there is some evidence for biochemical alteration in the mucoid chemistry of heavily infected oysters (Brun et al. 2000).

A recent report by Woods and Hayden (1998) associated the presence of a *Paravortex* sp. of turbellarian in the digestive diverticula with weakening and mortalities in the New Zealand scallop, *Pecten novaezelandiae*. Clinically, the scallops showed mantle retraction, gaping and impaired swimming behaviour prior to death. Prevalences of the *Paravortex* were greater in moribund scallops, but intensity of infections were low (<3 turbellarians per scallop) and not all affected scallops were infected. Other diseases, such as Malpeque disease of American oysters (*C. virginica*) have also been found to show a positive correlation with turbellarian proliferation (Drinnan, R.E., unpubl. data); however,

Figure 11.16. *Urustoma cyprinae* on the gills of giant sea scallop (*Placopecten magellanicus*) from Newfoundland. Hematoxylin and eosin stain. Scale bar = 1 mm.

this is believed to be a secondary, opportunistic proliferation, rather than a primary cause, due to inconsistencies between manifestation of disease signs and presence of the turbellaria. The ongoing work of Brun et al. (2000) may be able to shed some light on bivalve-turbellarian interactions at a physiological level. Documentation of effects at the predation level are more clear, for example *Pseudostylochus ostreophagus* predation on small juveniles of Japanese scallops (*Mizuhopecten* (*Patinopecten*) *yessoensis*) (Bower and Meyer 1994).

11.5.4 Nematodes

There is a lack of published information on parasitic larval nematodes of marine molluscs because they are difficult to identify and require special procedures, such as enzyme digestion, to isolate them from their embedded locations within bivalve tissues (Cheng 1978).

An abundant literature exists on the ascarid nematode, *Sulcascaris sulcata*, which infests larval scallops and, as an adult, inhabits the stomach of sea turtles, *Chelonia mydas* and *Caretta caretta* (Sprent 1977). Two scallops that serve as intermediate hosts are *Amusium balloti* and *Chlamys* sp. in Australian waters (Cannon 1978; Lester et al. 1980). Lichtenfels et al. (1978, 1980) and Blake et al. (1984) identified larval *S. sulcata* from the Atlantic scallops *Argopecten gibbus* and *A. irradians*. Parasitised green and loggerhead turtles occur in the same general area as the infected scallops.

The life cycle of *S. sulcata* starts with the release of negatively buoyant eggs from adult worms living in the intestine of the sea turtles. The eggs are shed with the turtle faeces, sink and adhere to the sea floor. After about 1 week, third stage larvae hatch and infect their molluscan host. Fourth stage larvae within the molluscs are ingested by the sea turtles and attach to the esophageal-gastric junction where they moult into adults within 7 to 21 days. Subsequent time to maturity takes at least 5 more months (Berry and Cannon 1981).

In Australia, scallop adductor muscle was infected, while all *S. sulcata* occurred in the gonad of *Argopecten gibbus* off the Atlantic coast of the United States. The worms are white and inconspicuous when small, and yellow to pale orange or brown when larger. There is cellular infiltration around the larvae, which usually lie loosely coiled near the surface of the adductor muscle. The presence of many larvae can damage the muscle enough to cause a loss of tonicity (Cannon 1978, cited in Berry and Cannon 1981).

The presence of nematodes, and the brownish capsule in which they are found, make some of the processed adductor muscles unsuitable for export. Up to 64% of commercially harvested saucer scallops, *Amusium balloti*, have been found to be infected by *S. sulcata* (Lester et al. 1980). Depending on whether an infected scallop is consumed cooked or raw, *S. sulcata* may be regarded as an aesthetic problem, or as a threat to public health. However, infectivity trials have failed to infect teleost or elasmobranch fish, or chickens or cats, thus, there is no evidence that they are a threat to human health (Berry and Cannon 1981) and no human cases of ascariidosis have been reported from consumption of infected scallops.

A small percentage of *Amusium balloti* were also infested with a larval gnathostome, *Echinocephalus* sp., and two other scallop species, *Anachlamys leopardus* and *Chlamys asperrimus*, were found to contain *S. sulcata* (Lester et al. 1980).

McLean (1983) identified second stage juveniles of *Echinoucinatus pseudouncinatus* from the adductor muscles of *Argopecten aequisulcatus* (*A. ventricosus*) from Baja California, Mexico. The worms measured 14 to 17 mm in length and were located within yellow or brown spots on the surface of the adductor muscle. The same species of nematode infects pink abalone (*Haliotis corrugata*) from California, and causes blistering of the foot. Heavy infections are associated with weakening of the foot, holdfast attachment and grazing capability (Sindermann 1990). The final hosts of *E. pseudouncinatus* are elasmobranch fish.

Another nematode *Porrocaecum pecten* reported in *Argopecten irradians* and *A. gibbus* is usually invisible macroscopically. However, brown discolouration of the worm occurs when it becomes infected by an unidentified haplosporidian hyperparasite (Cheng 1967, 1973, 1978; McLean 1983). This renders the worm visible and reduces the quality of the scallop meat.

11.6 POLYCHAETES

Even though polychaete worms do not generally penetrate the soft tissues of the bivalves that host their refugia, the excavation of their tunnels in the matrix of the bivalve shell can have a significant indirect impact on physiology and overall survival of the bivalve. In addition, the mud substrate used to line the tunnels created by the most common family of shell-dwellers, the polydoriids, can exacerbate the erosion effect. Subsequent enlargement of the tunnels creates opportunities for other polychaetes, which, unlike the relatively innocuous *Polydora* spp., are easily visible by consumers, e.g., *Ceratonereis tridentata* (Wells and Wells 1962) and *Nereis diversicolor* (McGladdery et al. 1993a). Shell damage and lively polychaete occupants can significantly impact live mollusc markets. Although this is not usually a factor for scallop meat markets, many

species are marketed in shell. Another effect of shell excavation is tunnel perforation of the inner shell surface - especially at the adductor muscle attachment site - which can create access for soft-tissue irritants, abrasion and secondary opportunistic microbial infection (see Section 11.2.2.3). Weakened adductor muscle attachment also impairs shell closure, swimming, feeding and escape behaviour in scallops. Bergman et al. (1982) reported that scallop shells weakened by *P. websteri* boring are more vulnerable to crushing by predatory decapods. The patterns of breakage among scallop (*Placopecten magellanicus*) shells damaged by rock crabs and lobsters suggest that successful predation is often accomplished by fracture of the upper valve near the umbo where the level of polydoriid infestation was generally high. It was unclear what effect shell infestation had on scallop natural mortality (Elner and Jamieson 1979). Turner and Hanks (1959) considered *P. websteri* infestation a contributing factor to unusually high mortalities of bay scallops in Fairhaven, Massachusetts. Polychaete burrows close to the scallop hinge may have interfered with the function of the adductor muscle, which in many cases was in poor condition. Similar damage to the same scallop species have been linked to *Polydora ciliata* and *Polydora* spp. by Russel (1973), Leibovitz et al. (1984) and Karlsson (1991).

The harmful effects of polychaete shell damage vary with the intensity of infestation and the type of burrow formed. The most obvious chronic effect is development of mud blisters. These form as sand or mud breach the nacre layer of the shell. Continuous erosion of non-peripheral surfaces is progressively walled off by conchiolin and nacre secretion from the epidermal tissues in contact with the irritant. Such effects from *Polydora concharum*, *P. socialis* and *P. websteri* are well documented for the giant sea scallop *Placopecten magellanicus* (Blake 1969; Evans 1969; Bergman et al. 1982; McGladdery et al. 1993b). Wells and Wells (1962) and Blake and Evans (1973) describe effects in bay scallops (*A. irradians*) from the eastern US, and Skeel (1979) described *Polydora* infections in four species of cultivated bivalves in Australia. *Placopecten meridionalis*, was infected with *P. websteri* which formed mud blisters between the shell and mantle. An alternative route for inducing such damage is polychaete larvae swimming into the mantle cavity and burrow between the shell and mantle, however, most evidence supports externally driven penetration to the inner surface. Shell damage at the peripheral edges can also induce mantle retraction and growth deformities (indentations, overgrown or double lipped edges, etc.). Regardless of route and site of irritation, this challenge can assume extreme proportions if it persists and the resultant mud blisters take over a significant percentage of the inner shell cavity (Fig. 11.17).

Mori et al. (1985) investigated the polydoriid infestation of scallops, in this case *Mizuhopecten (Patinopecten) yessoensis* in Japan. The boring polychaetes were identified as *Polydora variegata*, *P. ciliata* and *P. concharum* (Fig. 11.18). The worms settled almost exclusively on the left valve of these cultured scallops. Two years after seeding, the shell region nearest the attachment of the adductor muscle was heavily penetrated by polydoriid tunnels, which frequently contacted the muscle attachment surface. These authors suggested that these polydoriids could have a significant influence on the growth of scallops in that area. Similar observations have also been reported for this scallop species in Japan (Sato-Okoshi and Okoshi 1993), Russia (Kurochkin et al. 1986) and Pacific Canada (Bower and Meyer 1994). On the west coast of Canada shell damage

Figure 11.17. *Placopecten magellanicus* with extensive mud blisters occupying one third of the inner surface of the valve. Note poor condition of adductor muscle attachment site.

(thickening, growth stunting, impairment of adductor muscle function and associated mortalities) from a related species *P. websteri* is so severe that it renders culture of *M. yessoensis* impractical in some locations (Bower et al. 1994). Similar observations have recently been reported for polydoriid infestation of great scallop (Coquille St.-Jacques, *Pecten maximus*), spat from scallop nurseries in Norway (Mortensen et al. 1999). The spat measuring only 5–7 mm were found to have shells heavily infested by a *Polydora* sp. This infestation was associated with losses representing a third of Norway's cultured scallop production in 1997. Another polychaete, the tubeworm *Pomatoceros triqueto*, has been associated with fouling-related mortalities of up to 65% in the same scallop species in Ireland (Burnell et al. 1995).

Figure 11.18. Comparison of burrowing regions and morphology of burrows in three species of *Polydora*. (a) *P. variegata*; (b) *P. ciliata*; and (c) *P. concharum*. (After Mori et al. 1985).

A fouling spionid, *Sabella spallanzanii* has been reported on *Pecten fumatus* shells from Cockburn Sound, Western Australia by Clapin and Evans (1995). Resultant smothering losses have necessitated re-evaluation of suspension culture methods (O'Connor et al. 1999) and development of shell attachment methods (gluing) rather than cage-culture.

Cirratulids, such as *Dodecaceria concharum*, may occupy the empty burrows of *Polydora* spp. in the shells of *Placopecten magellanicus* (Evans 1969; Leibovitz et al. 1984). And sabellids, like *Pseudopotamilla reniformis*, have also been found in the shells of *P. magellanicus* from Maine. The large size of the worms (up to 100 mm) and the secretion of large ridges of shell material to contain them may be a potential problem for scallops with heavy infestations. Blake (1969) reported up to 30 worm tubes from a single *P. reniformis* infested scallop shell.

11.7 CRUSTACEA

11.7.1 Pinnotheriidae

Many species of pinnotherid crabs (also known as “pea crabs”) live symbiotically in the mantle cavity of marine bivalves. The scallops, *Argopecten irradians concentricus*, *A. gibbus*, and *Placopecten magellanicus*, are hosts for the species *Tumidotheres* (*Pinnotheres*) *maculatus* along the eastern US (Getchell 1991). Disease conditions associated with pinnotherid crabs include emaciation, reduced filtering capacity, damage to gills, palps, and mantle and compression of the gonad which may affect gonadal development. There are no observations of crabs feeding directly on host tissues, but their location within the mantle cavity inflicts a variety of host conditions ranging from slight irritation to severe structural alterations and pathology (Lauckner 1983).

Infestation with *T. maculatus* was found to cause stunting in *Argopecten irradians concentricus* from the eastern US. Bay scallops containing adult female pea crabs were slightly smaller than uninfested scallops. Growth of 3 size groups of scallops was measured over a 3 month period. Smaller scallops hosting pea crabs grew significantly less than uninfested scallops, although the larger scallops showed no significant difference between infested and uninfested groups (Kruczynski 1972).

Other scallops documented as hosting pinnotheriid crabs include *Amusium pleuronectis* (Llana 1979) and *Chlamys farreri* (Cheng 1967).

11.7.2 Copepodidae

Several copepod parasites have been reported from scallops. Reddiah and Williamson (1958) recorded *Paranthessius pectinis* and *Modiolicola inermis* from *Aequipecten opercularis* collected from around the Isle of Man, off the UK, as well as *Modiolocola maxima* from *Pecten maximus* in the same area. The effects of these copepod infestations were not reported as being significant. A similar *Modiolicola* sp. infestation of *Pecten maximus* from Norway was, likewise, not associated with pathological effect (Mortensen 1993b).

In contrast, *Pectenophilus ornatus*, a copepod parasite on the gills of the scallops, *Mizuhopecten* (*Patinopecten*) *yessoensis*, *Chlamys farreri nipponensis* and *C. f. farreri* from Japan (Nagasawa et al. 1988, 1991; Nagasawa and Nagata 1992) is associated with evident hypertrophy of the host tissue at the attachment site of the highly modified copepod (Fig. 11.19). The female assumes a modified sac-like morphology reaching 8 mm in diameter, resembling a rhizocephalan barnacle (Elston et al. 1985). The adult copepods are brilliant orange except for the area immediately surrounding the male vesicle which is reddish (Nagasawa et al. 1988). The parasite is devoid of appendages of any sort and is completely unsegmented. Its body is attached to the host by means of a tapering stalk (Fig. 11.19 and 11.20). The eggs are incubated within a spacious cavity communicating with the exterior by an unpaired birth pore through which the larvae are emitted. The nauplii closely resemble other copepod nauplii (Fig. 11.21). *Pectenophilus ornatus* feeds on the haemolymph of the scallop and may infest up to 100% of the cultured populations. It causes reduced marketability and decreased physiological condition. Combatting the parasite or controlling its distribution will depend on improved knowledge of its life cycle, reproductive dynamics and longevity.

11.8 GASTROPODS

The Family Pyramidellidae comprises a few small (3–5 mm in length) Odostomid gastropods which parasitise marine bivalves by feeding on haemolymph drawn from near the edge of the mantle or, in the case of clams, the siphon (Lauckner 1983; McGladdery et al. 1993a). Leibovitz et al. (1984) observed large numbers of the gastropod, *Odostomia* sp., on the sides of holding tanks, and on the valves, mantle, and pallial cavity of captive

Figure 11.19. *Patinopecten yessoensis* left valve with 15 small and large specimens of *Pectenophilus ornatus* attached to the left demibranchs. (After Nagasawa et al. 1988).

Figure 11.20. *Pectenophilus ornatus* sectioned in median plane. Microanatomy of female labelled as follows: b, birth pore; bl, blood lacuna; br, brood pouch; cm, midgut, central part; do, diverticulum of ovary; e, esophagus; ga, genital atrium; go, genital orifice; lm, lateral diverticulum; og midgut; mf, muscle fibres; mo, mouth; mv, male vesicle with two males; mvo, opening for male vesicle; o, unpaired part of ovary; p, pharynx; pc, pharyngeal channel; pp, pharyngeal pouch; sr, seminal receptacle; st, stalk. (After Nagasawa et al. 1988).

Figure 11.21. *Pectenophilus ornatus* nauplius in dorsal view. (After Nagasawa et al. 1988).

bay scallops (*Argopecten irradians*). Developing embryos of the gastropod were also found within the soft tissues. These authors associated these gastropods with high mortalities among their broodstock and experimental bay scallops, however, *Odostomium* spp. are considered to be relatively benign haemolymph predators in other species.

Odostomium seminuda was common on the upper valve of *Argopecten irradians* and on the 'ears' of *A. gibbus* from North Carolina (Wells and Wells 1961). Constant irritation of the calico scallop's mantle margin by penetration of the pyramidellids' proboscis during feeding reportedly resulted in retraction of the mantle in affected areas.

Another pyramidellid, *Turbonilla interrupta*, is known to attack scallops along the eastern North American coast (Morton 1967), however, no further details of pathology or distribution have been reported.

The common oyster drill, *Urosalpinx cinerea*, has demonstrated predatory behaviour in a laboratory study of attacks on bay scallop, *Argopecten irradians*. Predation resulted in 72.3% mortality. The snails also demonstrated a positive chemotactic response to scallop effluent in a choice chamber (Ordzie and Garofalo 1980).

11.9 ALGAE

Many algae have been labelled as symbionts of marine bivalves, e.g., *Zoochlorella* spp., which colonise the mantle, eyes, and tentacles of wild, captive and cultured adult bay (*Argopecten irradians*) and sea scallops (*Placopecten magellanicus*) south of Cape Cod. The infections produced green proliferative granulomatous lesions of the mantle and tentacles and haemocyte infiltration into the eyes. The disease was not seen in young scallops (Leibovitz et al. 1984).

Early work by Naidu (1971) showed another alga, *Coccomyxa parasitica*, to be parasitic on *Placopecten magellanicus* from Newfoundland. The peripheral mantle tissue, as well as portions of the gonad and adductor muscle when exposed to ambient light were affected. When infestation levels were high, there was a decline in the condition and weight of the viscera, including the adductor muscle. The mantle had a dark green colour, was slippery due to a layer of mucus, and had a musty odour. Histological work demonstrated the encapsulation of the algal colonies by a network of connective tissue fibres. Because the normal mantle morphology is disrupted, shell deformities consisting of extra shell margins and grossly warped valves may occur. Of almost 3,000 scallops sampled by Naidu (1971), 17.6% were found to be infested. Scallops 8–10 years of age had the highest prevalences, while no algal cells were found in scallops younger than 3 years of age. Levels of infestation were positively correlated with light intensity.

Stevenson and South (1975) have described the causative agent in detail. They also showed that endocytosis occurs throughout the infestation and contributes to the spread of the algal cells. The algae also enters through normal feeding by the scallop, but seems highly resistant to digestion. The algal cells do not appear to be highly pathogenic or cause a rapid death of the host. *Coccomyxa parasitica* infestations are restricted to shallow water populations of *Placopecten magellanicus* inhabiting the more northern latitudes of its range (Stevenson and South 1975).

Leibovitz et al. (1984) described a die-off of post-metamorphic juvenile cultured bay scallops (*Argopecten irradians*) in association with a bloom of the dinoflagellate, *Prorocentrum* sp. in a Long Island Sound hatchery's water supply. The juvenile scallops showed signs of distress including gaping shells, injuries to the soft tissues by the dinoflagellates' minute spines, and impaction of the pallial cavity. Melanisation of the resulting lesions in the mantle followed, with secondary invasion of bacteria and ciliates.

Around the same time many coastal embayments of Long Island, New York, experienced algal blooms during the summers of 1985 and 1986 that were unprecedented in their persistence and cell density ($>10^9$ /litre). Small microalga decreased light penetration to less than 1 meter, severely affecting eel grass (*Zostrea*) beds. The 1985 bloom coincided with the spawning period of the bay scallop (*Argopecten irradians*) and was blamed for the massive recruitment failure of that year-class (Casper et al. 1987). Transmission electron microscopy indicated that the responsible microalga was a previously undescribed species, similar to the chrysophyte species tentatively designated *Aureococcus anorexefferens*, which also bloomed in Narragansett Bay, Rhode Island in 1985 (Sieburth et al. 1986). Grazing experiments revealed that bay scallops were inefficient at retaining the 'brown tide' cells, but this alone does not account for the impact that was observed. Possible mechanisms investigated were toxicity effects, reduced ingestion rates, reduced absorption efficiencies at high densities and poor nutritional qualities of the brown tide alga (Casper et al. 1987).

Following a picoplankton bloom in Long Island Sound, NY, 1985, Bricelj et al. (1987) measured a 76% reduction in adductor muscle weight of adult bay scallops compared with 1984 data. However, survivors rebounded in September to triple their mean muscle weight. Mortality rates were not documented during either 1985 or 1986, thus, impact on survival is unknown.

11.10 FORAMINIFERANS

The calcareous foraminiferan *Cibicides refulgens* is a conspicuous and abundant component of the epifaunal community, living on the valves of the Antarctic scallop, *Adamussium colbecki*. One of its modes of nutrient acquisition is parasitism by eroding through the scallop's shell, and using dissolved free amino acids from the highly concentrated pool in the extrapallial cavity (Alexander and DeLaca 1987). These authors showed that 50% of attached *C. refulgens* significantly erode the surface of the scallop's shell to excavate channels into the extrapallial cavity. Whether the cumulative effects of *C. refulgens* induced shell erosions have a detrimental influence on the bivalve in the marginal Antarctic environment remains unknown, but seems likely. Hayward and Haynes (1976) reported the association of other foraminiferans including *Cibicides lobatulus* on the queen scallop *Aequipecten (Chlamys) opercularis*.

11.11 PORIFERA

As with polydoriid polychaetes, clionid sponges are also known as ubiquitous shell colonising organisms in both live and dead marine bivalves (Lauckner 1983). Shell

destruction follows excavation through etching and discarding of shell fragments to permit sponge proliferation and development of inhalent and exhalent passages throughout the shell.

Evans (1969) detailed the extent of shell destruction by *Cliona vastifica* in *Placopecten magellanicus* from Newfoundland, Canada. The radiographs of infested shells showed how little shell material was left between the inner and outer surfaces of heavily colonised individuals. Externally, clionid invasion of the shell can be identified by small holes which open into the inhalent and exhalent tunnels, usually starting at the hinge end of the shell with predominant damage to the ventral valve (Warburton 1958).

Clionid invasion of the shell may also effect the soft parts of scallops and cause a condition Medcof (1949) termed 'dark-meat'. The adductor muscles of affected individuals have a greyish brown tinge, are flaccid and stringy, and reduced in size. The meat yield of lightly infested scallops was about 59%, while that of heavily infested scallops was only 46% of the yield of healthy individuals. Off Digby, Nova Scotia, Canada, only those scallops 8 to 9 years or older were affected by clionid sponges. Invasion by the pest starts near the hinge and spreads until the entire shell is honey-combed with burrows. The shell can reach over 3 times its normal thickness because of repeated nacre deposition on the inner shell surface to attempt shell repair. Several other reports of *Cliona celata* and *C. vastifica* shell damage have also been reported from *P. magellanicus*, but most are not associated with adductor muscle discolouration (Evans 1969; Sindermann 1971; McGladdery et al. 1993a). Kurochkin et al. (1986) report clionid damage to the shells of *Patinopecten (Mizuhopecten) yessoensis* in the Sea of Japan/Peter the Great Sea. These infestations were also associated with soft-tissue retraction and reduction of physiological condition.

Leibovitz et al. (1984) described clionid induced shell deformities in juvenile and adult bay scallops (*Argopecten irradians*), probably caused by a *Scypha* sp. These are tubular sponges that attach to the internal surface of the valve, as well as the ventral margins and external surface. No significant mortalities were seen, so the fate of these deformed scallops is unknown. More recently, a reciprocal shell colonisation relationship was reported on *Aequipecten opercularis*, where the sponge *Siberites ficus* ssp. *rubrus* was associated with reduced shell colonisation by other fouling agents (Armstrong et al. 1999). Within the geographic range of this species, this provides a natural alternative to chemical/salinity/shock treatments for problem colonisation and may provide potential for aquaculture use to control shell matrix colonisation.

Several species of scallop have evolved a mutualism with epizooic sponges on their shells. The sponge protects the scallop from predatory starfish, while being protected from nudibranchs and/or deriving additional nutrients generated by the host's inhalant current (Bloom 1975; Forester 1979; Chernoff 1987; Pitcher and Butler 1987).

11.12 CNIDARIA

The colonial hydroid, *Hydractinia echinata*, a common inhabitant on the external surface of the shell of the sea scallop, *Placopecten magellanicus*, sometimes attaches to the internal shell surface. This intrusion interferes with the normal activities of the

scallop's mantle, often causing shell deformities. The scallop reacts by secreting a new shell edge within the existing perimeter and bypassing the hydroid colony. Batteries of nematocysts are abundant at the leading edge of the colony and the mantle withdraws presumably because of the discharge of the nematocysts into it. Successful control of this intrusion is accomplished when the scallop overgrows the impinging hydroid colony. No evidence has been found that *H. echinata* may ultimately cause the death of the scallop (Merrill 1967).

11.13 NON-INFECTIOUS DISEASES

In addition to the organisms that colonise scallops or cause infectious diseases, scallops also suffer from diseases that are not infectious. The most familiar cases are associated with aquaculture when animals are kept in suboptimal conditions, especially in land based systems, where diseases caused by bacteria (often *Vibrio* spp. as described in Section 11.2.2.1) can be encountered. Scallops cultured in open-water systems, however, have also encountered problems such as smothering by various organisms, including mussels (Minchin & Duggan 1989; Kurata et al. 1996) and barnacles (Ovsyannikova and Levin 1982). In wild stocks, abiotic factors, such as unknown environmental disturbances, were associated with abnormal melanisation and microstructural distortions of the shell of *Pecten maximus* in Brittany, France (Larvor et al. 1996). Anthropogenic pollutants have also been attributed to diseases affecting both cultured and wild stocks. For example, Syasina et al. (1996) and Usheva (1999) have described weakening muscle atrophy associated with necrosis and gametogenesis abnormalities in *Mizuhopecten yessoensis* from polluted areas of Peter the Great Bay, Sea of Japan. Also, Karaseva and Medvedeva (1994) reported embryo toxicity in the same species of scallop after parental exposure to copper and zinc.

11.14 SUMMARY

With growing interest in scallop enhancement, stock regeneration and molluscan aquaculture species diversification, comes a growing opportunity for improved health and disease understanding for these pectinids. Suspension culture, hatchery manipulated reproduction and increased proprietary observation is bound to reinforce the many gaps evident in this parasite, pest and disease summary. Many parasites, which have been reported in wild populations and subsequently forgotten, may become more readily available for study, or more problematic under culture conditions. In addition, the new tools being developed for other mollusc groups (primarily oysters) will be more accessible in the near future for distinguishing between significant scallop pathogens and innocent commensals - especially at the microbial level. With this in mind it is clearly anticipated that this chapter will also be superseded in the next 10 years - these authors look forward to reading it.

ACKNOWLEDGMENTS

The authors gratefully acknowledge the kind assistance of everyone who submitted images to illustrate the diseases described. Special thanks are due to Dr. Karin Lohrmann, Universidad Catolica del Norte, Facultad de Ciencias del Mar, Cas. 117, Coquimbo, Chile, for her valuable manuscript input as well as many images supplied during her doctoral thesis work at CEFAS, UK.

Chapter 12

Scallop Ecology: Distributions and Behaviour

Andrew R. Brand

12.1 INTRODUCTION

There are some 400 known living species in the bivalve family Pectinidae, commonly known as scallops. They occur in all the seas of the world from polar regions to the tropics. Most of the commercially important species occur in the inshore waters of the continental shelves but scallops are found in waters of all depths from the intertidal zone down to some 7,000 m.

Scallops are perhaps best known for their ability to swim – an unusual adaptation for a bivalve mollusc – and the swimming escape responses of species like *Argopecten irradians* (Lamarck), *Aequipecten opercularis* (L.), *Pecten maximus* (L.) and *Placopecten magellanicus* (Gmelin) have long been the subject of investigation (e.g., Verrill 1897; Buddenbrock 1911; Bayliss et al. 1930; Belding 1931; Gutsell 1931; Baird 1958; Caddy 1968; Waller 1969; Moore and Trueman 1971; Thomas and Gruffydd 1971; Thorburn and Gruffydd 1979). The swimming habit of scallops is thought to have evolved through modification of pre-existing mantle cavity cleansing mechanisms in byssally attached monomyarian ancestors (Drew 1906; Yonge 1936). Probably all scallops form a byssus for attachment when young (Verrill 1897) but many of the larger and more active species (e.g., *Mizuhopecten yessoensis* (Jay), *Pecten fumatus* (Reeve), *Pecten maximus*, *Placopecten magellanicus*) later become free-living on the seabed and lose the ability to secrete a byssus when they reach a larger size. Many small and delicate-shelled forms (e.g., *Chlamys vitrea* (Gmelin), *Chlamys furtiva* (Lovén)) and species living in areas of strong current flow (e.g., *Chlamys islandica* (O.F. Müller), *Mimachlamys varia* (L.)) are capable of releasing the byssus and making active swimming movements but generally remain attached throughout life. Some species, like the small European *Chlamys distorta* (da Costa) or the massive *Hinnites multirugosa* (Gale) of the Pacific coast of North America, swim freely in early life but later becomes cemented by the right valve to the rock and subsequent growth is irregular, the shell taking on the configuration of the surface to which it is attached (Yonge 1951). The scallops then, by virtue of the number of species, their geographical distribution and the range of habitats they occupy, are a supremely successful group of bivalve molluscs, and important members of a number of benthic communities. They are extremely attractive and prominent animals with many species of considerable commercial importance, the flesh being considered a luxury food in many countries. For these various reasons, scallops have been the subject of much scientific research. However, despite the vast literature, detailed knowledge of the

ecology is restricted to a few species and there are some surprising gaps in our understanding of other common species.

This chapter describes the geographical and local distribution of scallop populations, concentrating on the species of commercial importance. It also discusses various factors that affect distribution, including environmental conditions, ecological interactions with other species and relevant aspects of the behaviour of post-larval scallops, such as byssus attachment, orientations and movements. In reviewing current knowledge of these topics the aim is to present a comparative account of all species. The usual common names and geographical region of occurrence of the species referred to most frequently are given in Table 12.1. Of these, *Argopecten gibbus* (L.), *A. irradians*, *Aequipecten opercularis*, *Chlamys islandica*, *Pecten maximus* and *Placopecten magellanicus* are considered in the greatest detail because these commercially important species have received the most study.

Table 12.1

Common names and geographical region of occurrence of some commercially important scallop species.

Species	Common name	Geographical region
<i>Aequipecten opercularis</i>	Queen scallop	E. North Atlantic
<i>Aequipecten tehuelchus</i>	Vieira; Vieira tehuelche	W. South Atlantic
<i>Amusium balloti</i>	Southern saucer scallop	Indo-West Pacific
<i>Amusium pleuronectes</i>	Moon scallop	Indo-West Pacific
<i>Argopecten gibbus</i>	Calico scallop	W. North Atlantic, Gulf of Mexico
<i>Argopecten irradians</i>	Bay scallop	W North Atlantic, E. coast U.S.A
<i>Argopecten purpuratus</i>	Ostion	E. South Pacific
<i>Chlamys islandica</i>	Iceland scallop	Sub-arctic
<i>Equichlamys bifrons</i>	Queen scallop	S.W. South Pacific
<i>Mimachlamys asperima</i>	Doughboy scallop	S. Australia
<i>Mimachlamys varia</i>	Black; variegated scallop	E. North Atlantic
<i>Mizuhopecten yessoensis</i>	Yezo scallop; hotate gai	W. North Pacific
<i>Patinopecten caurinus</i>	Weather-vane scallop	E. North Pacific
<i>Pecten fumatus</i>	Commercial scallop	S. Australia
<i>Pecten jacobaeus</i>	Pilgrims scallop	Mediterranean
<i>Pecten maximus</i>	Great scallop; escallop; Coquille St. Jacques	E. North Atlantic
<i>Pecten novaezelandiae</i>	New Zealand scallop	New Zealand
<i>Placopecten magellanicus</i>	Sea scallop; giant scallop	W. North Atlantic

12.2 GEOGRAPHICAL DISTRIBUTION

12.2.1 Geographical Distribution of Commercially Important Species

While pectinids occur commonly in all seas of the world, the species that are of large enough body size and occur in sufficiently dense aggregations to be commercially exploited are found mostly in high latitudes, between about 30° and 55° in both northern and southern hemispheres. For the main commercially exploited species, the distribution of fishable concentrations has generally been well established, but even for these species, reliable information on the full geographical distribution is often remarkably scant. For each species there is a geographical and bathymetric range where environmental conditions are generally suitable for survival. Towards the extremities of their range, environmental factors such as water temperatures become limiting and scallops are scarce. Where conditions are favourable, scallops frequently occur in dense local populations, which may be of sufficient extent and density to support commercial fisheries. In the following account the geographical distributions of the most important commercial species are considered in an order based on geographical regions.

12.2.1.1 North Atlantic species

12.2.1.1.1 *Pecten maximus* and *P. jacobaeus*

The geographical distribution of the great scallop, *Pecten maximus*, is shown in Figure 12.1. This species occurs along the eastern coast of the North Atlantic from northern Norway south to the Iberian peninsula (Tebble 1966), and has been reported also off West Africa, the Azores, Canary Islands and Madiera (Mason 1983). It also extends a short distance into the Mediterranean for in some years there has been a small fishery for *P. maximus* off the Costa del Sol, extending from the mouth of the river Guadiaro as far east as La Caleta de Valez in the province of Malaga (Cano and Garcia 1985). Further east it is replaced by the closely related *P. jacobaeus*, which is heavily exploited in many places throughout the Mediterranean and Adriatic (Piccinetti et al. 1986; Mattei 1995). The bathymetric range of *P. maximus* is from just below the low water mark (Tebble 1966) to about 183 m (Forbes and Hanley 1853) but it is most common in water of 20–45 m. It is essentially a coastal species and occurs on bottoms of clean firm sand, fine gravel or sandy gravel, sometimes with an admixture of mud (Mason 1983). It occurs in sufficient densities for commercial exploitation in many relatively small locations off the coasts of France and the British Isles (Figure 12.1), but the principal fisheries are in the Baie de St. Brieuc, Baie de la Seine, eastern and western English Channel, the north Irish Sea all around the Isle of Man, the Clyde, West of Kintyre, Orkney, Shetland and the Moray Firth.

Figure 12.1. *Pecten maximus*. Principal fishing grounds around Britain and France (redrawn and modified from Mason 1983), together with the approximate geographical distribution of the species (inset).

12.2.1.1.2 *Aequipecten opercularis*

The other commonly exploited species in the eastern North Atlantic is the queen scallop, *Aequipecten opercularis*. This has a similar geographical range to *Pecten maximus* (Figure 12.2), having an approximate latitudinal range of 30°N to 70°N, but it extends further into the Mediterranean and Adriatic (Tebble 1966; Broom and Mason 1978; Piccinetti et al. 1986). It has a similar bathymetric range and is frequently found coincident with *Pecten maximus* on the same grounds but can live also on harder gravel and shelly bottoms because, unlike *Pecten*, it does not usually recess in the seabed (Mason 1983). The major aggregations that support commercial fisheries around the British Isles are relatively few in number and are widely separated (Rolfe 1973; Sinclair et al. 1985), notably in the western English Channel, Kish Bank, the north Irish Sea, Clyde, Orkney and Shetland, but it is abundant also in places in the North Sea, the Kattegat and around the Faroes (Ursin 1956).

12.2.1.1.3 *Mimachlamys varia*

A third European species, of some minor commercial value in France, is the black or variegated scallop, *Mimachlamys varia* L. (Letaconnoux and Audouin 1956; Shafee and Conan 1984). This small scallop is very common around the British Isles and has been reported from Denmark to the Iberian peninsula, in the Mediterranean and off the coast of West Africa to Senegal (Tebble 1966). It is widely distributed along the west coast of Ireland and is locally abundant within sheltered bays where it is found byssally attached to shells, stones, boulders or rock faces (Rodhouse and Burnell 1979). In the north Irish Sea it is a prominent member of the epifauna on banks of the horse mussel, *Modiolus modiolus*, together with *Chlamys distorta* (Jones 1951).

12.2.1.1.4 *Placopecten magellanicus*

On the western side of the North Atlantic the sea scallop, *Placopecten magellanicus* (Gmelin), has a geographical range that extends from Pistolet Bay, Newfoundland and the north shore of the Gulf of St Lawrence to Cape Hatteras, North Carolina (Figure 12.3) (Posgay 1957; Squires 1962; Bourne 1964). The usual depth range for this species is from 18–110 m but it occurs in shallower water in the northern part of the range and has been reported from depths as shallow as 2 m (Naidu and Anderson 1984). At the southern end of the range it is found in much deeper water, usually in excess of 55 m (Bourne 1964), while the known bathymetric range extends down to 384 m (Merrill 1959). Sea scallop populations of sufficient extent and density to support commercial fisheries occur from Virginia Capes (36°50'N) to Port au Port Bay, Newfoundland (48°40'N), with fishing grounds off Virginia Capes; off New York City; around Block Island, Rhode Island; on Georges Bank; off Cape Cod; along the coast of Maine; the Bay of Fundy, particularly off Digby, Nova Scotia; the southern Gulf of St Lawrence; Scotia Shelf (Browns Bank, Emerald Bank, Sable Island Bank, Banquereau); Port au Port Bay and St Pierre Bank (Bourne 1964; Naidu and Anderson 1984). Of these, the Georges Bank fishing grounds

are by far the most productive and have been exploited consistently for more than 50 years (Serchuk et al. 1979; Sinclair et al. 1985; Murawski et al. 2000).

Figure 12.3. *Placopecten magellanicus*. Principal fishing grounds (map kindly provided by S. E. Shumway).

12.2.1.1.5 *Argopecten irradians*

The bay scallop occurs along the eastern coast of the U.S.A. and is recorded from Cape Cod, Massachusetts to the Laguna Madre, Southern Texas (Clarke 1965) (Figure 12.4), but present day distributions are not as extensive as previously reported. Three subspecies have long been recognised, based on shell morphometrics (Clarke 1965; Waller 1969). The geographical variation in morphology would appear to have a strong genetic basis (Wilbur and Gaffney 1997) but genetic variation may not coincide with variations in the morphological criteria used in subspecies designation (Bricelj et al. 1987b; Blake 1994; Blake and Graves 1995) and further studies are required to clarify the taxonomic status of some populations. The northern subspecies, *A. i. irradians*, extends

Figure 12.4. *Argopecten irradians*. Approximate geographical distribution of the three subspecies along the eastern coast of the U.S.A. (Redrawn and modified from Broom 1976).

from the north shore of Cape Cod, Massachusetts (42°N) to the area between New Jersey and Maryland (39–40° N) where it intergrades with *A. i. concentricus* (Clarke 1965). This subspecies then extends south, but is now uncommon on the Atlantic coast of Florida, and into the Gulf of Mexico where the most reliable westerly record of its presence is around the Chandeleur Islands of Louisiana (29°N 88°W) (Waller 1969; Broom 1976). Surprisingly for such a prominent and easily cultured bivalve, the western limit of *A. i. concentricus*, and the degree to which it intergrades with the most southerly subspecies, *A. i. amplicostatus*, is not well known. *A. i. amplicostatus* itself has been reported to occur from Galveston, Texas (26°N 95°W) to the Laguna Madre, southern Texas (26°N 97°W) (Waller 1969), but the southern limit of this subspecies is not known. A fourth subspecies, *Argopecten irradians taylorae*, with a restricted distribution in Florida Bay and west of the Florida Keys, has been proposed (Petuch 1987), but subsequent genetic and morphometric analyses have failed to separate this from Florida populations of *A. i. concentricus* (Marelli et al. 1997). As the common name implies, the bay scallop is found in protected coastal bays, sounds, estuaries and the inshore sides of barrier islands. It generally occurs very close inshore, in water of less than 12 m, typically on sandy substrates amongst the eelgrass, *Zostera*, though it does extend down to about

20 m (Belding 1931; Gutsell 1931; Marshall 1960; Sastry 1962; Cooper and Marshall 1963; Bologna and Heck 1999; Peterson et al. 2001).

12.2.1.1.6 *Argopecten gibbus*

The calico scallop, *Argopecten gibbus*, is closely related to the bay scallop; it is found also in the western North Atlantic and the Gulf of Mexico but in deeper water further offshore. It has a more southerly distribution, with a geographical range extending from the northern side of Greater Antilles (about 18°N) and throughout the Gulf of Mexico to Bermuda, and slightly north of Cape Hatteras, North Carolina (36°N) (Allen and Costello 1972) (Figure 12.5). Its precise southerly limit and distribution in the West Indies is unknown due to taxonomic confusion with other species, such as *A. nucleus*, which has an overlapping distribution extending from southeastern Florida to the coasts of Colombia and Venezuela (Waller 1969). *Amusium papyraceum*, *A. laurenti* and *Euvola zic-zac* are also commercially exploited at different places within the Caribbean (Penchaszadeh and Salaya 1985) but these species are of limited local importance and are not the subject of major fisheries, like *Argopecten gibbus*. Calico scallops are most abundant near coastal prominences; the largest, commercially fished concentrations occur over a large area off the east coast of Florida, near Cape Kennedy, though the location of individual scallop beds varies from year to year.

Lesser concentrations are found near Cape Lookout, North Carolina and in the northwest Gulf of Mexico near Cape San Blas, Florida. More sporadically fished grounds have also been reported off Savannah, Georgia and along the west coast of Florida from off Egmont Key to Key West (Cummins 1971; Allen and Costello 1972; Allen 1979). The calico scallop is found in warm, open marine waters and has been classified as a subtropical tolerant species (Miller and Richards 1980). It has been reported to occur in depths of less than 2 m down to 277 m but the commercial concentrations generally occur from about 20–70 m (Waller 1969; Allen and Costello 1972), with the largest concentrations off Cape Kennedy at depths of 33–42 m (Miller and Richards 1980).

12.2.1.2 Sub-arctic species

12.2.1.2.1 *Chlamys islandica*

The distribution of the Iceland scallop overlaps with that of *Placopecten magellanicus* in the western North Atlantic, though the two species apparently occur together on the same beds only on St. Pierre Bank, the westward extension of the Grand Banks of Newfoundland (Naidu and Anderson 1984). *C. islandica*, however, is a sub-arctic species, with its main distribution in the sub-arctic transition zone (Ekman 1953). On the western side of the Atlantic *C. islandica* occurs in greatest abundance in the Straits of Belle Isle, along the Labrador shelf, St Pierre Bank and over most of the Grand Banks (Naidu et al. 1982), but it has also been reported in fishable concentrations from as far south as Nantucket, Massachusetts (41° 32'N) (Naidu and Anderson 1984) and to occur as far north as the Parry Islands (75°N) (Wiborg 1963). It is found along East and West

Figure 12.5. *Argopecten gibbus*. Approximate geographical distribution (stippled areas) and principal fishing grounds (black areas). (From Allen 1979).

Greenland, around Jan Mayen and Iceland, and in the eastern North Atlantic and Arctic oceans Iceland scallops occur along the Norwegian coast, mainly north of the Arctic Circle, western and northern Spitzbergen, Bear Island, Hopen Island, Murman coast, White Sea, west coast of Novaya Zemlja and the Kara Sea (Ockelmann 1958; Wiborg 1963; Lubinsky 1980; Hansen and Nedreaas 1986; Sundet and Fevolden 1994). *C. islandica* has also been recorded from the Bering Strait and extends into the Pacific Ocean, the Okhotsk Sea and down the eastern Pacific coast as far south as Puget Sound (Mottet 1979). However, Waller (1991) considers that *C. islandica* is limited to the sub-arctic regions of the North Atlantic and the records from the North Pacific region are due to taxonomic confusion with closely related species. *C. islandica* is found mainly in depths of 10–110 m, though it has been taken in trawl catches down to 525 m (Hansen and Nedreaas 1986). In Newfoundland, fishable concentrations occur mainly in waters deeper than 55 m, on hard bottoms with variable substrate composition consisting of sand, gravel, shell fragments and stones (Naidu and Anderson 1984). Wiborg (1963) comments that the densest populations along the Norwegian coast are found in fjords with one or more

sills at the entrance, in places with comparatively strong currents. This latter observation was noted also by Naidu (1982) for Iceland scallop populations in the Gulf of St. Lawrence.

12.2.1.3 North Pacific species

12.2.1.3.1 Patinopecten caurinus

The weathervane scallop, *Patinopecten caurinus* Gould, is found in the eastern North Pacific. It occurs along the west coast of North America from San Francisco (37°N) to the Gulf of Alaska (60°N) and extends also into the Bering Sea (Grau 1959; Mottet 1979; Bernard 1983). It has been fished commercially off the coast of Alaska since 1967 (Haynes and Powell 1968; Haynes and McMullin 1970), initially off Kodiak and Yakutat, but extending later to grounds off Dutch Harbor and other areas such as south-east Alaska, Cook Inlet, Alaska Peninsula, the Bering Sea and Prince William Sound (Kruse and Shirley 1994; Shirley and Kruse 1995; Kruse et al. 2000). Large commercial concentrations were found off Coos Bay, Oregon in 1981 but were depleted in one year (Starr and McCrea 1983). Small beds have occasionally been exploited in the region of Puget Sound and it is frequently taken incidentally in other fisheries off the coasts of Canada, Washington and Oregon. *P. caurinus* has been reported from the intertidal zone down to depths of 300 m, but is most abundant between 45–130 m on beds of mud, clay, sand and gravel (Hennick 1973; Kruse and Shirley 1994).

12.2.1.3.2 Mizuhopecten yessoensis

On the western side of the North Pacific several species of scallops are the subject of important commercial fisheries off the coasts of Japan, Korea and Russia. Of these, *Mizuhopecten yessoensis* is by far the most important and, with the decline of natural fisheries in the 1960's, enormous quantities of this species have since been produced in both hanging and seabed culture (Ventilla 1982; Ito 1991). *M. yessoensis* is a cold water species that occurs around Hokkaido and the northern part of Honshu Island, with a natural distribution that extends as far south as Tokyo Bay on the Pacific coast and Toyama Bay in the Sea of Japan. It is found also in the Kurile Islands, the Sea of Japan along the coasts of Korea and the USSR, off Sakhalin Island and extending north into the Sea of Okhotsk (see distribution maps in Ito 1991). The Japanese commercial fisheries were mainly confined to the Okhotsk Sea coast of Hokkaido, Volcano Bay and Mutsu Bay in Aomori but, with the development of culture techniques, scallops are now produced in other areas further south (Motoda 1977). Fishing and cultivation of *M. yessoensis* in Russia is mainly in the Primorye region, south Sakhalin and the southern Kurile Islands (Kalashnikov 1991). *M. yessoensis* is a coastal species, commonly found in water of up to 40 m in depth but a maximum depth of 82 m has been reported in Peter the Great Bay (Skarlato 1981). It occurs where the bottom is fairly hard, with little mud (Imai 1980).

12.2.1.3.3 *Pecten albicans*, *Mimachlamys nobilis* and *Chlamys farreri*

These three species are of commercial value for fishing or cultivation in Japan and elsewhere in the western North Pacific, but they are not as abundant as *Mizuhopecten yessoensis* (Ventilla 1982). *P. albicans* Schröter and *Mimachlamys nobilis* (Reeve) are predominantly southern species found in shallow inshore reef areas, from the southern part of Hokkaido in Japan to Korea, Taiwan and China, with *M. nobilis* extending as far south as Indonesia (Ito 1991; Lou 1991). *Chlamys farreri* (Jones & Preston) has been reported from the north of the Japanese island of Honshu (Ventilla 1982) to the Fujian province in China at latitude 25° N (Lou 1991). Its distribution is patchy along the coast of China but it is fished and cultivated in many locations.

12.2.1.4 Southern hemisphere species

12.2.1.4.1 *Pecten fumatus*

Compared with the northern hemisphere, the geographical distribution of scallop species in the southern hemisphere is not so well known. There are established fisheries for several species of scallops around the coasts of Australia, in both the temperate and tropical regions (Figure 12.6) (Gwyther et al. 1991). Large commercial scallops of the genus *Pecten* occur from Newcastle, New South Wales, southward to Bass Strait, around Tasmania, all along the south coast and up the west coast as far north as Shark Bay (Fairbridge 1953; Olsen 1955; Young and Martin 1989). In the past these were considered to be four different species on the basis of shell morphology: *Pecten fumatus* (Reeve) occurring in New South Wales, *P. alba* (Tate) in Victoria and South Australia, *P. (= Notovola) meridionalis* (Tate) in Tasmania and *P. modestus* (Reeve) in Western Australia. However, electrophoretic studies of protein variation suggest that at least the first three of these are synonymous and should be included in the single species complex, *P. fumatus* (Woodburn 1987, 1989; Gwyther et al. 1991), known locally as the commercial scallop. The western limit of the distribution of *P. fumatus* and the southern and eastern limits of *P. modestus* are unclear. Throughout its range *P. fumatus* occurs in enclosed bays like Jervis Bay and Port Phillip Bay, as well as in exposed oceanic situations like the Banks Strait. It occurs on bottom substrates varying from muddy sand to coarse sand, in depths of 7–60 m. *P. modestus* occupies similar habitats in Western Australia, where it is found in 14–22 m depth in Cockburn Sound and 16–35 m in Geographe Bay. Important fishing grounds for *P. fumatus* have been located in Port Phillip Bay, off Lakes Entrance, in the Bass Strait, off the Furneaux Group and in several areas around the coast of Tasmania, including D'Entrecasteaux Channel. None of these grounds have supported a fishery for a very long period before the stocks have been depleted (Anonymous 1984b; Pontin and Millington 1985; Gwyther 1989; Young and Martin 1989) and, despite management efforts to stabilise these fisheries, annual production is very variable due to the irregularity of recruitment (Gwyther et al. 1991; Coleman 1998). There have also been small fisheries for *P. fumatus* in southern New

Figure 12.6. Scallop species exploited around the coasts of Australia.

South Wales (Jervis Bay and Bermagui) and central South Australia (Coffin Bay and Boston Bay), and for *P. modestus* in Cockburn Sound in Western Australia.

12.2.1.4.2 *Mimachlamys asperima* and *Equichlamys bifrons*

In some areas of Australia commercial scallops are fished together with the doughboy scallop, *Mimachlamys asperima* (Lamarck), and the queen scallop, *Equichlamys bifrons* (Lamarck), but these scallops are of minor commercial importance (Pontin and Millington 1985; Young and Martin 1989; Wolf and White 1995). *Mimachlamys asperima* is by far the most abundant of these two species and in many areas it is more common than the commercial scallop, *Pecten fumatus*. It is distributed from Geographe Bay in Western Australia, around Southern Australia and Tasmania to the New South Wales coast (Figure 12.6) (Young and Martin 1989). It occurs in similar habitats to *Pecten fumatus*, in depths ranging from 7–69 m, but is usually byssally attached throughout life to solid objects within the bottom substrate. *Equichlamys bifrons* is found in waters of 2–40 m deep off New South Wales, Victoria, South Australia and Tasmania. It occupies a similar habitat to the other two species but is most common on coarse bottom substrates. In shallow bays of the D'Entrecasteaux Channel and Huon river estuary, *E. bifrons* is almost completely restricted to seagrass beds and rarely occurs on adjacent sandy areas (Wolf and White 1997). Unlike *M. asperima*, the adults do not remain byssally attached but recess into shallow depressions in the seabed.

12.2.1.4.3 *Amusium balloti* and *A. pleuronectes*

In the tropical and subtropical waters of the Indo-Pacific several species of the genus *Amusium* are fished commercially. *A. balloti* and *A. pleuronectes* are common species with wide distributions throughout the region, the latter being recorded from the Indian Ocean, South China Sea, Indo-China, Japan, the Philippines, New Guinea, Indonesia, Java and Australia (Morton 1980). The Australian stocks of each have been assigned to two subspecies: the southern saucer scallop *Amusium japonicus balloti* (Bernardi) and the moon scallop *Amusium pleuronectes australiae* Habe.

The geographical range of *A. j. balloti* in Australia extends from Hervey Bay in southern Queensland, around the north and west of tropical Australia to Esperance on the south coast of Western Australia (Young and Martin 1989). It is found in water of 10–75 m depth but is most abundant at 25–55 m. It is fished commercially by otter trawlers in Queensland in the region from Mackay to the southern end of Fraser Island (21°S to 25°S) (Dredge 1985a; Dichmont et al. 2000). The same species is also fished in Western Australia, where it occurs in commercial densities in Shark Bay, around the Abrothos Islands and as far south as Rottnest Island (32°S) (Anonymous 1984a; Anonymous 1984b; Joll and Caputi 1995).

Amusium pleuronectes has a wide distribution around northern and western Australia but is found in shallower water than *A. balloti*. In Northern Queensland it is most abundant on firm, sandy, carbonate bottoms in depths of 12–24 m. It is fished commercially over a wide area, mainly as a by-catch of prawn trawlers, but particularly off Darwin in the Northern Territory and Admiralty Gulf in Western Australia (Sanders 1970; Young and Martin 1989). *A. pleuronectes* is the most common and abundant species of scallop in the Philippines where it occurs on sandy-mud to mud bottoms at 18–40 m depth (Llana 1983, 1985; Del Norte 1991). It is also common along the continental shelf of southern China, and Morton (1980) suggests that it migrates into the shallow coastal waters of Hong Kong to breed since it occurs in the markets only in the winter months when it is sexually mature.

12.2.1.4.4 *Pecten novaezelandiae*

In the temperate waters of New Zealand, *Pecten novaezelandiae* occurs sporadically around the entire coastline including Stewart Island and the Chatham Islands (34°S – 47°S). It is found on a wide variety of substrates in semi-estuarine and coastal waters from low tide to at least 90 m (Bull 1991). It is fished commercially in various locations but the main beds are at the north end of South Island (Golden Bay, Tasman Bay and the Marlborough Sound) and the north of North Island (Bream Bay, Spirits Bay, the Bay of Plenty, Hauraki Gulf) (Tunbridge 1968; Bull 1989, 1991). Since 1989, a rotational fishing regime, coupled with extensive stock enhancement, has been operated with great success in Tasman Bay and Golden Bay to stabilise the fishery and achieve environmental and commercial sustainability (Arbuckle and Metzger 2000; Dredge et al. 2002).

12.2.1.4.5 *Argopecten purpuratus* and *A. ventricosus*

The oston, *Argopecten purpuratus* Lamarck, is a scallop of considerable commercial importance in the eastern Pacific, its range extending on both sides of the equator. It is fished and cultivated in Chile and Peru (Wolff and Wolff 1983; Wolff 1988; Piquimil et al. 1991; Stotz 2000; Wolff and Mendo 2000). The natural distribution of this species is from Corinto, Nicaragua (12°30'N) to Valparaiso, Chile (33°S), occurring in semi-protected bays with sedimentary substrates (Grau 1959; Waller 1969; Piquimil et al. 1991), however it has been introduced for cultivation into sheltered bays much further south (Gonzalez et al. 1999). According to Olsson (1961), it is a typical cold-water scallop of the Humboldt current, occurring most abundantly along the coast of Peru, southward from the Bay of Sechura. The distribution of *A. purpuratus* overlaps with that of the more northerly *Argopecten ventricosus* Sowerby (previously but erroneously called *Argopecten circularis* (Waller 1995)), which extends from Paíta, Peru (5°S) to Monterey Bay, California (37°N) (Grau 1959; Waller 1969). *A. ventricosus* is particularly abundant in some sheltered locations on both the Pacific and Gulf coasts of Baja California, where it is fished by divers who also exploit *Pecten vogdesi* and *Nodipecten subnodosus* in some areas (Félix-Pico 1991; Félix Pico et al. 1999). This latter species is now considered to have great potential for cultivation in Mexico, due to its large size and fast growth rate (Félix-Pico et al. 2003; Racotta et al. 2003)

12.2.1.4.6 *Aequipecten tehuelchus*

Aequipecten tehuelchus (d'Orbigny) was for many years the only scallop in the southwestern Atlantic that was commercially exploited. It is a warm temperate species that ranges from Rio de Janeiro, Brazil (23°S) to Camarones, Argentina (45°S), with commercial densities occurring mostly at depths greater than 15 m (Ciocco 1991; Orensanz et al. 1991b). The fishery is mostly confined to the San Matías and San José Gulf's and has developed strongly since 1968. However, annual landings are highly variable due to irregular recruitment, intense harvesting and sporadic catastrophic stranding mortalities caused by storms (Iribarne et al. 1991; Orensanz et al. 1991b).

12.2.1.4.7 *Zygochlamys patagonica*

Z. patagonica is a cold temperate species of the continental shelf of Patagonia (Orensanz et al. 1991b), with an extensive distribution off the coasts of Chile (Piquimil et al. 1991), Argentina (Waloszek 1991; Lasta and Bremec 1997) and Uruquay (Gutierrez and Defeo 2003). It extends from Puerto Montt (41°S) in the Pacific Ocean south to Cape Horn and northwards in the Atlantic Ocean from the Burwood Bank and the Falkland Islands to the estuary of the Rio de la Plata (36°S) (Waloszek 1991). Off the coast of Chile it occurs from 2–40 m in protected bays, inlets and channels (Piquimil et al. 1991), but on the Argentinian and Uruquayan shelf it has a very extensive offshore distribution with the main concentrations from 60–80 m depth (Orensanz et al. 1991b; Lasta and Bremec 1997). There is a long-established dive fishery for *Z. patagonica* in Chile

(Piquimil et al. 1991), but the extensive offshore populations on the Argentinean shelf have only been exploited by dredging since 1996 (Lasta and Bremec 1999).

There are other species of scallop that occur in abundance but their geographical distribution is not well known as they have not been commercially exploited or are remote from areas of regular scientific activity. For example, in the southeastern Atlantic, stocks of *Pecten sulcicostatus* have been surveyed off South Africa that may prove to be worth exploiting (de Villiers 1976). Further south, the Antarctic scallop, *Adamussium colbecki*, has a circumpolar distribution with a depth range that extends from just below the sea ice to 1500 m (Dell 1972; Berkman 1991). The highest densities are usually found in shallow water near to shore (Stockton 1984), but other factors such as the persistency of sea ice also play a part (Chiantore et al. 2001). Antarctic scallops have never been exploited and, as pointed out by Berkman (1991), this makes them useful baseline measures for assessing the potential impacts of human activities.

12.2.2 Factors Affecting Geographical Distribution

The geographical distribution of a species depends on many interrelated factors but for most marine animals temperature is the primary factor that limits the overall geographical range. Temperature can directly or indirectly affect the survival of larvae and adults, and is known to influence reproduction though its effects on gamete maturation, spawning, embryonic development, the length of planktonic life and larval settlement (Kinne 1970). There is a very large literature concerning the effects of temperature on the ecology, physiology and distribution of marine organisms (e.g., see Kinne 1970; Newell 1970; Hawkins et al. 2003), including many studies on scallops.

Placopecten magellanicus is a cold-water species with a temperature optimum of about 10°C (Posgay 1953). Dickie (1958) found the upper lethal temperature for this species to range from 20–24°C, depending on the acclimation temperature. He also found that the upper lethal temperature is raised quite rapidly (1.7°C per day) by acclimation to higher temperature, but the loss of acclimation to high temperature is very slow and appears to take as long as 3 months. Sudden increases or decreases in temperature, too small to be lethal, both caused debility, the scallops gaping, secreting large quantities of mucus and becoming quiescent. Dickie and Medcof (1963) and Bourne (1964) discuss the ecological relevance of these findings. At the northern end of the range *Placopecten* occurs in shallow depths, where the water is warmest. The distribution in this part of the range is apparently determined largely by low summer temperatures, which fail to reach the spawning threshold or prolong larval development, resulting in recruitment failure. In the more southerly part of the range, sea scallops live at greater depths where the water remains cold, separated from the warm surface layers by a thermocline. It has been suggested that many of the sudden mass mortalities of sea scallops that have been reported on beds at intermediate or shallow depths in the south-western Gulf of St Lawrence result from perturbations to the position of the thermocline which subject scallops to sudden large changes in temperature (Dickie and Medcof 1963). These may be of sufficient extent and duration to be the direct cause of death but, more often, thermal shock increases mortality indirectly by inhibiting the scallop's normal escape reactions and

making them more vulnerable to predation. Such reactions will cause complex interactions between predator and prey species, depending on their respective thermal tolerances.

A similar experimental study of upper temperature tolerance was carried out by Paul (1980b) on the queen scallop, *Aequipecten opercularis*. He also found that the upper lethal temperatures (LD50-48h) increased markedly in the range 19–25°C depending on the acclimation temperature. By investigating the responses of three size groups he was also able to show that very young queens were more resistant to high temperatures than animals of intermediate or large size (Figure 12.7) and showed less effect of acclimation. The greater thermal resistance of young animals agrees with previous findings for some other groups (Huntsman and Sparks 1924; Brett 1956).

Paul (1980b) also carried out experiments to study the effects of temperature on the rate of byssus formation in *Aequipecten opercularis*, which he found to be at a maximum at 18°C. This corresponds fairly closely with the results of McLusky (1973), who found that the rates of oxygen consumption and filtration were at a maximum at 15°C but fell sharply at 20°C, which he suggested was near the upper lethal temperature for this species. Ursin (1956) made a detailed study of the distribution of *A. opercularis* populations in relation to environmental temperatures. He suggests that temperatures below 2 or 3°C are lethal, since North Sea populations were severely affected when winter temperatures fell to this level in 1947. In the area he investigated, *Aequipecten* was not found at localities where summer temperatures normally exceed 17°C. The temperature range of 2–17°C is characteristic of a boreal species but *Aequipecten opercularis* extends also into the Mediterranean and Adriatic, where it is widely distributed in shallow water and must experience temperatures of 13–26°C. The Mediterranean form appears to be morphologically different to the boreal and the environmental differences suggest that they may also be physiologically distinct.

Environmental temperature appears also to play an important part in determining the geographical distribution of *Chlamys islandica*. This sub-arctic species generally occurs in temperatures ranging from -1.3°C to 8°C and Wiborg (1963) considers that its disappearance from areas where it was once abundant is due to the steady rise in temperature in northern waters, which began in about 1930. Similarly, the geographical distribution of *Argopecten gibbus* is probably limited primarily by temperature (Waller 1969). This species is one of a faunal assemblage in the northern Gulf of Mexico that occurs in waters deep enough to avoid winter cooling (Parker 1956). The temperature range for *A. gibbus* is given as 9.9°C to 33°C (Waller 1969; Allen and Costello 1972), but Vernberg and Vernberg (1970) found that calico scallops collected off North Carolina, near the northern end of their range, did not survive 48 hours at experimental temperatures of 10°C and suggest that the species has tropical affinities.

The geographical distribution of many scallop species is clearly associated with the thermal characteristics of the major ocean current systems. Thus, the cold Labrador current allows the southward extension of the sub-arctic *Chlamys islandica* down the western Atlantic coast, while its junction with the Gulf Stream in the region of Cape Hatteras marks the southern limit of *Placopecten magellanicus* and the northern limit of *Argopecten gibbus*. Similarly, in the western Pacific, the current systems determine the

Figure 12.7. Temperature tolerance of *Aequipecten opercularis*. Median lethal temperatures (LD_{50} 48-h) for three size groups (A, >60 mm; B, 30–40 mm; C, 5–10 mm shell height), acclimated to different temperatures. The dashed line shows where acclimation temperature = median lethal temperature. (From Paul 1980b).

geographical distribution of scallop species around the coast of Japan. *Mizuhopecten yessoensis* occurs naturally in the regions influenced by cold currents in the winter and warm currents in the summer (for maps showing these currents see Ito 1991). This species cannot tolerate high temperatures and the temperature range for survival appears to be 5–23°C (Ventilla 1982). The ecological effect of temperature as a limiting factor

has been dramatically demonstrated by the very high mortalities obtained during attempts to cultivate *M. yessoensis* in the south of Honshu, where water temperatures in May and June exceed 22°C. In contrast, high mortalities of the warm water *Chlamys nobilis* can occur in winter if the temperature falls below the low temperature survival threshold of 8°C.

While temperature is obviously a major factor determining the overall geographical range of a scallop species, it interacts with numerous other factors such as water depth, substrate type, food availability, salinity, turbidity and the occurrence of competitors and predators in determining the local distribution. For species, like scallops, in which the mobility of the adult is very limited, the geographical distribution of a population is likely to be governed mainly by barriers to the dispersal of the larvae (Macleod et al. 1985). Patterns of water movement and other hydrographic features are therefore likely to be of major importance. Furthermore, since scallops have relatively long-lived pelagic larvae, the spatial and temporal stability of scallop populations will be dependent on the nature and stability of the hydrographic regime. The interplay of these various factors results in the local aggregation of scallops into particular areas of high density within their geographical range, which is a characteristic feature of scallop populations.

12.3 LOCAL DISTRIBUTION

12.3.1 Spatial Distribution

All scallop species have an aggregated distribution within their geographical range but before discussing the nature of spatial distribution patterns it is necessary to define the general terms used here to describe the scale or magnitude of aggregations. As shown in Figures 12.1, 12.2, 12.3 and 12.5, for four commercially fished species, there are a limited number of major areas within the geographical range of each species where the population is sufficiently abundant to support a commercial fishery. Such areas will be referred to as 'grounds' and are usually widely separated by areas that are environmentally unsuitable for the species. For example, the Western Channel, the north Irish Sea, the Clyde and West of Kintyre are *Pecten maximus* grounds, which are typically large areas separated by tens or even hundreds of kilometres. The absolute size of a ground may vary enormously, from an isolated bay of a few km², to the Georges Bank ground for *Placopecten magellanicus* which has an area of more than 31,000 km². Within each ground there is usually a number of regions, typically of an area of several km², where scallop abundance is higher than elsewhere, which will be referred to as 'beds'. Beds may be permanent aggregations, precise in their location and separated by clearly demarked areas that are unsuitable for scallops, or they may be temporary aggregations that vary in their location from year to year, resulting from uneven settlement or early survival. Finally, within each bed, the distribution of scallops may be aggregated into 'patches', the scale of which is generally measured in terms of tens or hundreds of m². It must be stressed that the terms 'grounds', 'beds' and 'patches' are used here simply to indicate the general scale of aggregation and are not intended to be precise definitions of the scale, absolute density or nature of spatial pattern, all of which may differ considerably between species or between

locations. More detailed consideration of the spatial structure of scallop populations is given elsewhere (Orensanz 1986; Caddy 1989; Orensanz et al. 1991a), with some variation in terminology. The terms used here are obviously convenient for describing aggregations of exploited species but are not so appropriate for the less abundant non-commercial species.

For each species the major grounds are generally widely separated geographically, and environmental conditions are usually sufficiently different to produce marked and frequently consistent differences in population parameters. For example, differences in growth rate between grounds have been reported for *Pecten maximus* (Mason 1983), *Placopecten magellanicus* (Bourne 1964), *Aequipecten opercularis* (Taylor and Venn 1978), *Aequipecten tehuelchus* (Ciocco 1991) and *Mizuhopecten yessoensis* (Yamamoto 1975), and differences in breeding cycles between grounds have been described for many species (Sastry 1970, 1979; Taylor and Venn 1979; Mason 1983; Paulet et al. 1988). There are also frequently differences in population size- and age-structure that arise partly from differences in the regularity of recruitment. This raises the important question of whether the populations of scallop grounds are self-sustaining. Scallops have fairly long-lived pelagic larvae and it has been often considered that dispersion is an important adaptive function of the larval phase of relatively sedentary benthic invertebrates (e.g., Thorson 1946; Thorson 1950). For scallops, however, the extent of larval dispersal and the origin of spat settling on a ground are not known for any species and are difficult to investigate. The general assumption that recruitment to scallop populations is derived mainly from larvae transported, often large distances, from surrounding areas (Posgay 1979b) has important implications to the strategy of fishery management, but is based on little evidence. These questions have been discussed in detail by Sinclair et al. (1985), who review the available evidence for *Aequipecten opercularis*, *Pecten maximus* and *Placopecten magellanicus*. They note that, for each of these species, the major fishing grounds are relatively few in number, of characteristic absolute abundance, precise in their geographical location and have been persistent in these locations for very long periods, all of which, they believe, strongly implies that the populations on these grounds are self-sustaining. They go on to point out that many of these scallop aggregations are found in areas with tidally-induced oceanographic features, relatively persistent gyres or characterised by two-layer circulation, all of which could provide mechanisms for larval retention. Naidu and Anderson (1984) consider that estuarine entrainment-type circulation systems (Tully and Barber 1960) are responsible for retaining scallop larvae over the parent grounds in many coastal populations around Newfoundland. For the calico scallop, gyres created by coastal prominences are considered to be responsible for retaining larvae (Allen 1979; Miller et al. 1981). The effects of water circulation and oceanographic fronts on larval transport and recruitment of *Pecten maximus* and *Aequipecten opercularis* in the north Irish Sea has been frequently discussed (e.g., Beaumont 1982a; Macleod et al. 1985; Duggan 1987), and areas with particularly good recruitment and growth of *Pecten* appear to correspond with the position of major fronts (Murphy 1986). Elsewhere, potential larval dispersal pathways and recruitment links have been predicted by hydrographic modelling (Darby and Durance 1989; Dare et al. 1994), and these studies conclude that localised scallop fisheries vary in the extent to

which they are likely to be self-sustaining. In recent years the techniques of biochemical genetics have been brought to bear on these problems, initially with studies of allozyme variation and, more recently, using DNA-based molecular methods, and there is now increasing evidence to suggest that many scallop populations may be largely self-recruiting.

For *Aequipecten opercularis*, the extent to which populations are reproductively isolated has been studied in a number of investigations of intraspecific biochemical genetic variation (Beaumont and Gruffydd 1975; Mathers 1975; Beaumont 1982a, b; Beaumont and Beveridge 1984; Macleod et al. 1985; Duggan 1987; Lewis and Thorpe 1994a, b). On the basis of mean genetic identities at nine sample sites, together with a consideration of current systems, Beaumont (1982a) suggested that there are at least four relatively genetically isolated populations of *A. opercularis* throughout its geographical range: a North Atlantic population extending from Northern Ireland through the north and west coasts of Scotland to Norway; a Celtic Sea population extending from the west coast of Ireland to the west coast of Brittany; an English Channel population and an Irish Sea population. Subsequent studies by Macleod et al. (1985) and Duggan (1987) generally agreed with Beaumont's suggestion of Irish Sea homogeneity in showing an apparent uniformity of allele frequencies in samples from different *A. opercularis* beds around the Isle of Man. However, the appearance of a rare allele in the 1979 year-class (*Pgi* allele 4), which later appeared also in spat of the 1984 year-class and very rarely in some other year-classes, suggests that there may be occasional recruitment of larvae from elsewhere. Interestingly, Mathers (1975) found significant differences in allele frequencies between queen scallop populations from the east and west coasts of Ireland, and his west coast sample may have contained the same rare allele that appeared in the 1979 and 1984 year-classes in the Isle of Man, indicating potential gene flow between these sites. Beaumont and Beveridge (1984) studied a sample of *A. opercularis* taken from an area near Anglesey, N. Wales. While the allele frequencies they obtained did not differ significantly from those obtained for populations around the Isle of Man (Duggan 1987), they found an additional allele at one locus that was not found in the Isle of Man samples. This suggests that the Anglesey ground may be to some extent genetically isolated from the grounds further north. In a more recent study, Lewis and Thorpe (1994a, b) investigated allele frequencies for each year-class in 12 populations of *A. opercularis* from around the UK. They found highly significant variations between sites, but allele frequencies between year-classes were predominantly homogeneous within sites. This temporal genetic stability within geographically highly heterogeneous populations suggests that queen scallops may be predominantly self-recruiting.

Studies of genetic variation have also been carried out on various other scallop species including *Argopecten irradians* and *Argopecten gibbus* (Blake 1994; Krause et al. 1994; Blake and Graves 1995), *Chlamys islandica* (Fevolden 1989, 1992), *Mizuhopecten yessoensis* (Kijima et al. 1984; Wilbur et al. 1997) and *Pecten maximus* (Beaumont et al. 1993; Wilding et al. 1997, 1998; Heipel et al. 1998, 1999; Ridgway and Dahle 2000).

In the work on *Pecten maximus*, initial allozyme studies failed to show any differentiation between 13 widely scattered populations in the British Isles and France, suggesting that these stocks might be regarded as a panmictic unit (Beaumont et al. 1993).

However, more recent studies using high-resolution DNA-based methods have shown that the British and Norwegian scallop populations belong to different gene pools (Ridgway and Dahle 2000), and that the Mulroy Bay population is significantly different from other UK populations (Wilding et al. 1997, 1998; Heipel et al. 1998). Mulroy Bay is a very enclosed body of water with restricted tidal transfer of water in and out, which could potentially cause the retention of larvae and self-recruitment. In the mid 1980's there was a dramatic decrease in scallop spat settlement in Mulroy Bay, linked to the use of tributyltin (TBT) on salmon nets. While the scallop populations have subsequently recovered, following a ban on the use of TBT (Minchin et al. 1987), this event could have been responsible for the low genetic diversity of the Mulroy Bay scallops. In addition to these more pronounced differences, a low but significant degree of genetic differentiation has also been found between commercially fished beds of *Pecten maximus* around the Isle of Man (Heipel et al. 1998, 1999), indicating some restriction to genetic exchange in relatively closely-located, open-sea populations.

Comparative studies of reproduction and larval development of *Pecten maximus* in the Bay of Brest and the Bay of St. Brieuc, France, including transplant experiments, have shown differences in reproductive pattern between the two bays that are genetically determined (Paulet et al. 1988). Similarly, scallops transplanted from Scotland also retained critical features of their reproductive cycle after growing in the Bay of St Brieuc for two years (Ansell et al. 1988; Cochard and Devauchelle 1993; Mackie and Ansell 1993). These transplant studies provide strong evidence for the existence of different stocks, despite the failure of allozyme studies to confirm genetic differentiation (Beaumont et al. 1993). In this case allozyme methods, which examine only a small proportion of the entire genome, were less able to detect stock differentiation than studies of the reproductive physiology. Despite these limitations, the techniques of biochemical genetics, particularly the high-resolution DNA-based methods, clearly have much to offer and more detailed surveys covering larger geographical areas, including populations with different patterns of recruitment, will be especially valuable for assessing the extent to which populations on different grounds are self-sustaining.

Different beds within a scallop ground would not normally be expected to be genetically isolated, though in inshore areas there may well be hydrographic mechanisms that cause larval retention within a very small area. Environmental conditions such as water depth, substrate type and food availability can vary considerably between beds, even within a small area, leading to differences in growth rates and breeding cycles. *Pecten maximus* and *Aequipecten opercularis* populations on different beds in the north Irish Sea have been frequently shown to differ in various population parameters (e.g., Mason 1957, 1958; Gruffydd 1974a, b; Murphy 1986; Allison 1993), and similar results have been obtained for many other species.

The shape and size of a bed may be constant, defined by physical or topographic factors such as the distribution of a suitable substrate, or they may be variable from year to year, depending on both the spatial distribution of settlement within an otherwise suitable area and the subsequent effects of fishing. On heavily exploited grounds, scallop aggregations are of temporary duration as fishing both reduces scallop abundance and causes scallops to disperse (Robert and Jamieson 1986). Caddy (1970), surveying scallop

grounds in the Northumberland Strait from a submersible, noted high-density aggregations of *Placopecten magellanicus* of at least 0.25–1.0 km in diameter, but on some grounds scallop beds can be very much larger. On Georges Bank, for example, *P. magellanicus* beds can be more than 30 km long yet often only 4 or 5 km wide (Jamieson 1978). This long and thin shape appears to be characteristic of scallop aggregations in several species, for it has been described also for *Amusium balloti* (Heald and Caputi 1981; Dredge 1985b), *Argopecten gibbus* (Cummins 1971; Roe et al. 1971; Allen and Costello 1972), *Mizuhopecten yessoensis* (Goshima and Fujiwara 1994), *Pecten fumatus* (Olsen 1955) and *Pecten novaezelandiae* (Tunbridge 1968). These authors all note that the long axis of these aggregations is parallel to the flow of tidal currents or to the depth contours, and the suggestion has frequently been made that beds of this shape arise by the concentration of larvae settling out in regions of strong current flow. There are some similar observations for other benthic invertebrates. Fager (1964), for example, reported an elliptical-shaped bed of the polychaete *Owenia fusiformis* and attributed this to the passive accumulation of larvae by hydrodynamic processes associated with a local rip current. Scheltema (1986) also illustrates how an elliptical distribution of settling larvae could result from the process of eddy-diffusion, acting together with horizontal advection in a current. There is evidence for the importance of hydrodynamic processes that result in passive accumulation and deposition of benthic invertebrate larvae at large spatial scales (Butman 1987). Such processes may well operate to produce large scallop aggregations. However, the species of scallop for which long, thin beds have been recorded are all very active swimmers. Various studies have shown a predominant downstream dispersal during swimming movements (e.g., Belding 1931; Bourne 1964; Moore and Marshall 1967; Gruffydd 1976b; Imai 1980; Posgay 1981; Minchin and Mathers 1982; Melvin et al. 1985; Goshima and Fujiwara 1994) and this would also lead to elongated patterns of distribution in areas of strong current flow.

The location of beds within large fishing grounds, and changes from year to year, can be determined by mapping the distribution of catch per unit effort as an index of scallop abundance. This requires detailed information from commercial fishing boats on the location of catches, or very extensive research vessel surveys. There are very few fisheries for which sufficiently detailed catch data of either type are available. The large fisheries for *Pecten maximus* and *Aequipecten opercularis* in the north Irish Sea have been studied in this way since 1981, based on catch and effort data reported by commercial fishermen for a 5 x 5 nautical mile (9.3 x 9.3 km) grid (Murphy 1986; Allison 1993; Beukers-Stewart et al. 2003). More detailed studies of the spatial distribution of *Placopecten magellanicus* over Georges Bank have been carried out using Canadian fishermen's logbook data, which allows catches to be attributed to one-minute squares of latitude and longitude (1.38 x 1.85 km at 42°N). Isopleth mapping techniques have been used on these, and on research vessel survey data, to produce contour maps of scallop abundance (Jamieson and Chandler 1981; Robert and Jamieson 1986). More recently, video survey techniques have also proved to be a fast and accurate way of determining scallops abundance and mapping the location of beds (Thouzeau et al. 1991; Stokesbury 2002).

The distribution of scallops within a bed has been frequently described as patchy for most species of scallop including *Adamussium colbecki* (Berkman 1991), *Aequipecten opercularis* (Soemodihardjo 1974; Mason et al. 1979b; Mason 1981), *Amusium balloti* (Heald and Caputi 1981), *Argopecten gibbus* (Cummins 1971; Allen and Costello 1972), *A. irradians* (Belding 1931; Tettelbach 1991), *Chlamys islandica* (Vahl 1981), *Mimachlamys varia* (Shafee 1979), *Mizuhopecten yessoensis* (Goshima and Fujiwara 1994), *Pecten fumatus* (Olsen 1955), *P. maximus* (Baird and Gibson 1956; Mason 1983), *P. novaezelandiae* (Tunbridge 1968) and *Placopecten magellanicus* (Bourne 1964; Caddy 1970, 1975; Stokesbury and Himmelman 1993; Stokesbury 2000). The densities of individuals in a patch can be exceptionally high: Mason (1983), for example, once found *Aequipecten opercularis* in layers three or four deep at a density of 500–1,000 scallops m^{-2} . Such dense patches are exceptional, however, even for this species. Some examples of the densities reported for different species of scallop are given in Table 12.2. Because of the aggregated distribution patterns, at different spatial scales, density estimates depend very much on the area over which they are measured. Methods for estimating densities on the scale of fishing grounds therefore generally give much lower estimates than the techniques appropriate for measuring small-scale patches (Orensanz et al. 1991a). However, average densities for many exploited species are usually in the range 0.1–10 scallops m^{-2} on a good fishing ground.

The spatial distribution of scallop species has rarely been investigated using methods appropriate for the study of biological pattern (see Andrew and Mapstone 1987), mainly because of inherent problems in the methods for capturing or observing scallops in their natural habitat. Dredge surveys do not provide sufficient resolution for studies of small-scale spatial distribution patterns (Caddy 1970; Mason et al. 1982). To do this it is necessary to use more quantitative techniques, such as diver quadrant counts (Olsen 1955; Vahl 1981; Caddy 1968) or underwater photography or television, taken from a towed sled (Caddy 1975; Franklin et al. 1980b; Thouzeau and Hily 1986; Thouzeau et al. 1991; Goshima and Fujiwara 1994) or from a submersible (Caddy 1970; Langton and Robinson 1990). These methods all have some advantages and disadvantages, depending on the aim of the study (Mason et al. 1982). Vahl (1981) used diver quadrant counts to study the spatial distribution pattern of *Chlamys islandica* on a bed in Balsfjord, North Norway. He used the variance to mean ratio test (Elliot 1971) to show that the distribution was not random, but highly contagious, and went on to demonstrate a good agreement with the negative binomial distribution. Similar statistical techniques have been applied to photographic surveys of *Placopecten magellanicus* and have also shown contagious distributions, even at low densities (Caddy 1970; Langton and Robinson 1990). Stokesbury and Himmelman (1993, 1995a) and Stokesbury (2000) have carried out the most detailed investigations of scallop distribution pattern, at different spatial scales, in studies of two *Placopecten magellanicus* beds in Port Daniel Bay, eastern Canada. At a large scale (km), scallop distribution was contagious and strongly associated with gravel or gravel-sand substrates, although not all gravel substrates contained high densities of scallops. At a small scale (cm), distribution was also contagious, with the scallops aggregated into small clumps. The average clump size was 1.13 m^2 in one bed and 4.5 m^2 in another, and the majority of scallops (79% in one bed

Table 12.2

Some estimates of density recorded for different scallop species.

Species	Location	Density (numbers m ⁻²)	Reference
<i>Aequipecten opercularis</i>	English Channel	mean 0.46; max. 4.46	Franklin et al. 1980b
	Guernsey	5.7	Askew et al. 1974 (unpubl.).

	Georges Bank	0.25–0.59	Stokesbury 2002

* These values were originally recorded in other units but have been converted here to number per m²

and 87% in the other) were in clumps. In the two beds, the average number of scallops per clump was about three, both sexes were present in 79% of clumps of adult scallops, and 91% and 75% of nearest neighbour pairs were 100 cm or closer. The authors suggest that this small-scale aggregation is an adaptation to increase fertilisation success, and warn that disturbance to these aggregations, as occurs during fishing (Langton and Robinson 1990), may decrease reproductive success. A small-scale random distribution, in agreement with the Poisson distribution, has been reported for some scallop populations (e.g., Mason et al. 1982; Thouzeau et al. 1991; Goshima and Fujiwara 1994) but, as pointed out by Andrew and Mapstone (1987), the spatial pattern observed using these methods depends on the scale at which the population is sampled, relative to the scale at which it is aggregated. In contrast to the findings of Stokesbury and Himmelman (1993), MacDonald and Bajdik (1992) reported a small-scale contagious distribution in a low-density bed of *Placopecten magellanicus* and a random distribution in a high-density bed. They suggest that sea scallops form local aggregations at low densities if food supplies are not limiting, but distributions become random at high densities as scallops attempt to reduce competition for resources by spacing themselves out. The mechanisms responsible for the establishment and maintenance of such small-scale aggregations are not known, though Stokesbury (2000) considers that swimming in *Placopecten magellanicus* may have evolved so that individuals could form clumps in order to enhance reproductive success, as well as to escape from predators. Clearly, more research is required on this subject.

12.3.2 Year-class Separation

Scallop beds frequently show a regional separation of year-classes that is probably largely a consequence of spatial differences in settlement and early survival. In heavily exploited species, this can lead to the concentration of the fishery on aggregations of the recruiting year-class (Caddy 1975; Murphy 1986) and the subsequent rapid depletion of stocks in that area. Year-class separation has been reported for *Amusium balloti* (Heald and Caputi 1981), *Aequipecten opercularis* (Soemodihardjo 1974), *Pecten maximus* (Gruffydd 1974a; Minchin and Mathers 1982; Mason 1983; Murphy 1986; Brand and Murphy 1992; Allison 1993), *Pecten fumatus* (Olsen 1955) and *Placopecten magellanicus* (Bourne 1964; Caddy 1975; Fritz and Haven 1981; Robert and Jamieson 1986; Thouzeau et al. 1991). Gruffydd (1974a) found regional variations in population age structure of *Pecten maximus* in unexploited areas of the north Irish Sea which indicated uneven recruitment, though taken over the whole area investigated recruitment was remarkably consistent from year to year. Subsequently, Murphy (1986) and Allison (1993) noted differences in the strength of particular year-classes between grounds to the east and to the west of the Isle of Man which could result from annual variations in the northerly flowing residual currents affecting larval dispersal to these grounds. For *Placopecten magellanicus*, isopleth mapping of survey catch rates for scallops of different ages has allowed the spatial distribution pattern of different year-classes on Georges Bank to be determined (Robert and Jamieson 1986; Thouzeau et al. 1991).

It has been suggested that scallop larvae may be gregarious (Mason 1983), that settlement patterns may depend on the distribution of suitable primary settlement sites like hydroids and bryozoans (Larsen and Lee 1978; Brand et al. 1980; Dare and Bannister 1987; Minchin 1992), and that density dependent mechanisms can affect recruitment success (Vahl 1982). However, the recruitment processes leading to spatial differences in year-class distribution are poorly understood, for any scallop species, due to the difficulties of studying the larval and pre-recruit stages in the field. Pectinid larvae are difficult to identify to species (Rees 1950; Le Pennec 1974, 1980; Gruffydd 1976a; Slater 2003), and are not easy to distinguish from the larvae of some other bivalve families, like the anomids and the mytilids, which are often abundant in the plankton. Settled spat and pre-recruit juvenile scallops are difficult to collect in representative abundance and, in accounting for their distribution, it is generally impossible to distinguish between differential larval settlement and differential post-settlement mortality. Following primary settlement from the plankton, juvenile pectinids can detach the byssus and swim or crawl short distances. This may be to escape from predators, or in some species it could be a re-dispersion strategy used by spat to find more favourable microhabitats after settling initially on unsuitable substrata (Wallace 1982). Experiments carried out on *Chlamys islandica* suggest that resettling spat show an aggregation response to spat that has already settled (Harvey et al. 1993). The possibility of scallops settling in nursery areas, where conditions are particularly favourable for settlement and early survival, and migrating or dispersing later to adult beds has often been suggested but until recently there was little evidence of this occurring in any species. Of the earlier work, Vahl (1981) showed delayed recruitment to a population of *Chlamys islandica*, and Allen (1953) reported inshore settlement followed by a possible offshore movement in the deepwater *Chlamys septumradiata*. Thouzeau et al. (1991) found that juvenile (age 1) *Placopecten magellanicus* were concentrated on gravel and pebble sediments in the northern half of Georges Bank and there was a clear dispersion to the south (age 2) and the south-west (age 3+) as they grow older. More recently, a tagging study of juvenile *Chlamys islandica* demonstrated movement into deeper water (Arsenault et al. 2000). This provides the first experimental evidence of juvenile scallops swimming from a nursery area to recruit into the adult populations, for the scallop movements in this study were predominantly downslope and could not be attributed to downstream advection. Recent studies by Kamenos and Moore (2003) suggest that maerl beds may act as nursery areas for juvenile *Aequipecten opercularis*.

12.3.3 Factors Affecting Local Distribution

Many of the factors affecting local distribution have been mentioned above in accounting for the observed patterns of spatial distribution. Environmental factors such as temperature, depth, food availability, substrate type, water currents, turbidity, oxygen concentration and salinity are all likely to be important, as are ecological interactions with competitors and predators. There have been very few experimental studies carried out under controlled conditions to determine the effects of any of these factors on scallop growth, reproduction or survival, so it is generally impossible to assess the ecological

significance of particular factors. Indeed, since all are interrelated in a complex manner it is of limited value to study single factors in isolation.

12.3.3.1 Depth

Depth is an important factor influencing many aspects of the biology of scallop species (Shumway and Schick 1987) but its ecological effects are usually associated with variations in temperature, food availability or substrate type (Dickie and Medcof 1963; Gruffydd 1974b; Leighton 1979; Posgay 1979a; Wallace and Reinsnes 1984, 1985; MacDonald and Thompson 1985a, b, 1986a). *Argopecten gibbus*, for example, has been reported in waters varying from 9.9–33.0°C (Waller 1969; Allen and Costello 1972) but temperatures outside the range 15–27°C are probably lethal to the major portion of the population (Miller et al. 1981). This restricts the species to a well-defined depth range off Cape Kennedy, with the largest concentrations occurring in 33–42 m (Miller and Richards 1980). However, irregular intrusions of deep, cold, water on to the Florida-Hatteras shelf affect both the local distribution and the abundance of calico scallop stocks (Miller et al. 1981). Similarly, temperature variation with depth accounts for the different depth distribution of *Placopecten magellanicus* along its geographical range (Bourne 1964), and populations in areas with unstable hydrographic conditions may suffer sudden mass mortalities when exposed to rapid temperature changes caused by oscillations in the depth of the thermocline (Dickie and Medcof 1963).

Reduced food availability with increasing depth from 19 to 31 m was considered to be a primary factor regulating growth, reproductive output and reproductive effort of *P. magellanicus* in Newfoundland (MacDonald and Thompson 1985a, b, 1986a, b, 1987). Populations of sea scallops living at much greater depths (170–180 m) in the Gulf of Maine have greatly reduced shell and tissue growth, compared with populations in shallow water (Schick et al. 1988). Barber et al. (1988) also found lower fecundities in these populations. This suggests that the deepwater populations are not self-sustaining but depend instead on sporadic recruitment from populations in shallower water (Shumway and Schick 1987). Nutrient stress was also considered to be a main factor accounting for the absence of *Aequipecten opercularis* from areas below 200 m (Ursin 1956).

12.3.3.2 Substrate type

Most scallop species are found on a range of bottom substrates but the important commercial species typically occur on harder substrates of gravel and coarse to fine sand (e.g., Mason 1983; Young and Martin 1989; Thouzeau et al. 1991; Stokesbury and Himmelman 1993; Dare et al. 1994). Indeed, the association of scallops with such deposits is so strong that high-resolution acoustic bottom discrimination techniques are increasingly being used to map scallop grounds and provide more precise estimates of scallop abundance (Burns et al. 1995; Magorrian et al. 1995; Kaiser et al. 1998; Kostylev et al. 2003). Many species, such as *Amusium pleuronectes* (Young and Martin 1989), *Argopecten gibbus* (Allen and Costello 1972), *A. irradians* (Belding 1931; Gutsell 1931), *Pecten maximus* (Mason 1983), *P. fumatus* (Young and Martin 1989) and *Placopecten*

magellanicus (Bourne 1964) are able to tolerate some silt or mud in the substrate but, even for these species, the areas of highest abundance and the fastest growth rates are normally areas with little mud. Such bottom substrates typically occur in areas of strong current flow.

12.3.3.3 Currents

Mason (1983) comments that *Pecten maximus* and *Aequipecten opercularis* are most abundant just inside or just away from areas of strong currents. There are very strong tidal currents in the English Channel and Dare et al. (1994) found a clear inverse relationship between *Pecten maximus* distribution and the magnitude of frictional bottom stress, with virtually all commercial scallop grounds restricted to areas where bottom stress is low (less than 10 dynes cm⁻²). Ursin (1956) classifies *A. opercularis* as a current dependent species, and associations with strong currents have been noted for many other species including *Argopecten irradians* (Belding 1931), *A. gibbus* (Allen and Costello 1972), *Chlamys islandica* (Wiborg 1963; Naidu et al. 1982), *Mizuhopecten yessoensis* (Imai 1980), *Pecten fumatus* (Fairbridge 1953; Olsen 1955) and *Placopecten magellanicus* (Bourne 1964).

Areas with strong currents generally provide favourable conditions for benthic filter feeders but there is now much experimental evidence to show that feeding and growth of *Placopecten magellanicus*, *Argopecten irradians* and *Chlamys islandica* are inhibited at very high rates of flow (Kirby-Smith 1972; Wildish et al. 1987, 1992; Wildish and Kristmanson 1988; Eckman et al. 1989; Wildish and Saulnier 1992, 1993; Claereboudt et al. 1994; Arsenault et al. 1997). Pilditch and Grant (1999) carried out a detailed investigation of the effects of variable food supply on *P. magellanicus*, measuring clearance rates while manipulating both flow velocity and phytoplankton concentration. They found that, with constant phytoplankton concentration, clearance rates during declining flow rates (15–5 cm s⁻¹) were 30% higher than during increasing flow rates (5–15 cm s⁻¹) and suggest that these elevated clearance rates during declining flow may compensate for the period of feeding inhibition they found at peak flow velocity (25 cm s⁻¹). The ecological implications of feeding inhibition in high current flows are not clear, however, for the behaviour of recessing into depressions in the seabed may enable *Placopecten magellanicus* and other scallop species to take advantage of boundary layer effects and avoid the high current velocities in apparently unsuitable areas (Yager et al. 1993; Stokesbury and Himmelman 1995b). In *Chlamys islandica*, Arsenault et al. (1997) found that the use of crevices to avoid predation resulted in higher growth rates for small individuals (15–30 mm shell height), but had no detectable effect on larger individuals (30–60 mm). They concluded that the markedly lower current velocities within crevices increased the feeding efficiency of small animals, since the velocity threshold at which feeding is inhibited is generally lower in small individuals. For *Argopecten irradians*, swimming responses operate to maintain position within eelgrass beds (Winter and Hamilton 1985), where current speeds are significantly reduced (Eckman 1987).

Like feeding, larval settlement and byssal attachment of spat are also likely to be physically limited, at some level, by high water current velocity but, while there are some

field observations, there are few experimental data for this for any scallop species. The settlement, growth and early survival of *A. irradians* in eelgrass beds have been studied by Eckman (1987) in relation to hydrodynamics. He found that newly settled larvae were significantly more abundant in areas with a lower density of eelgrass shoots, and consequently with higher rates of seawater flux. The subsequent growth and survival of *Argopecten* was more difficult to interpret but indicated the importance of hydrodynamic processes. Survival was generally low in regions with strong currents, suggesting that young *Argopecten* are dislodged from their byssal attachment to the eelgrass blades at higher current velocities. However, in this and numerous other field studies of bay scallop survival in seagrass beds (e.g., Pohle et al. 1991; Ambrose and Irlandi 1992; Ambrose et al. 1992; Bologna and Heck 1999), it is difficult to distinguish any effects of water currents from the effects of predation. Recently, Irlandi et al. (1999) showed that neither seagrass patch size nor plant density – both factors that affect the rate of current flow over the seabed – had any relationship with the survival of *Argopecten* over periods of 3–7 weeks, though there were significant short-term (i.e., 24 h) effects. They suggested that this lack of a longer-term relationship was due to differential responses to patch size by the many potential predators of juvenile scallop. Current speed and turbulent mixing have been shown to affect the efficiency with which predators prey on scallops. Thus, Powers and Kittinger (2002) found that whelk predation on bay scallops increased with increases in water flow, while blue crab predation decreased. They conclude that current speed and turbulent mixing affect the chemosensory abilities of both the predator to locate the scallop, and the scallop to detect and avoid approaching predators, with predator success depending on whether the predator or the prey is most affected.

12.3.3.4 Turbidity

Living in open coastal environments with coarse bottom substrates and relatively high current flow, most commercially important scallop species are not normally confronted with water of high turbidity. Other species, like the inshore, estuarine, *Argopecten irradians* and the many deepwater species, like *Chlamys septumradiata* (Allen 1953), commonly live on soft muddy bottoms and must be adapted for dealing with more turbid conditions. The shallow, subtidal, *Minnivola pyxidatus* is able to survive in dredged and trawled waters with high levels of settling and resuspended silt off the coast of Hong Kong, and elsewhere in the Western Pacific, but its numbers are declining locally because of seabed perturbations (Morton 1996). Increases in the amount of particulate inorganic matter in the water have been shown to have a detrimental affect on absorption efficiency and growth of *Chlamys islandica* (Vahl 1980; Wallace and Reinsnes 1985), and ciliary activity of *Mizuhopecten yessoensis* (Yamamoto 1956b), but there have been no experimental studies of the effects of turbidity on survival for these or any other scallop species. It seems likely, however, that turbidity is an important ecological factor that limits the occurrence and distribution of both adults and newly settled larvae. Scallop spat is very susceptible to silt and to low oxygen tension (Belding 1931; Yamamoto 1956b, 1960; Motoda 1977). The reduced water current velocity in the boundary layer just above the surface of the sediment allows the deposition of fine particles and organic detritus; the

oxidation of this organic material can then lead to the local depletion of dissolved oxygen in this layer. Yamamoto (1960) considered that such conditions are a major cause of mortality of the spat of *Mizuhopecten yessoensis* when they first release the byssus and turn to bottom life at a size of 6–10 mm shell length. He reported high mortalities of spat, amounting to 82–100% in some habitats, occurring in the summer and early autumn when the water temperature is high but mortality decreasing in the winter when the water temperature falls and the spat have reached a shell length of 30–40 mm. He concluded that mortality during this stage of the life history is most important in determining the size of the adult population, and that the recruitment of young scallops in any year depends on the presence or absence of an anaerobic layer. The habit of settling on algae, erect bryozoans or other surfaces would appear to provide scallop spat with a clean, silt-free surface raised above the boundary layer (Brand et al. 1980; Paul 1981; Dare and Bannister 1987; Harvey et al. 1993, 1994). The distribution of suitable sites for larval settlement and early survival may therefore be a major factor determining the local distribution of adult scallops.

12.3.3.5 Salinity

Salinity is another ecological factor that clearly acts to limit distribution, but there have been few studies of distribution in relation to salinity or of the salinity tolerance of scallop species. Most scallops live in fully saline water and species such as *Argopecten gibbus*, *Argopecten purpuratus* and *Aequipecten opercularis* do not survive well in reduced salinities. *Argopecten gibbus* occurs where the salinity is fairly stable and ranges from 31–37‰ (Allen and Costello 1972). *Argopecten purpuratus* is stenohaline and natural beds of this species occur in bays along the Chilean coast where salinity fluctuations are generally low (34.5–35.2‰). Uribe et al. (2003) believe that the scarcity of *A. purpuratus* at the extremes of its range results from lower salinities to the north of Païta, Peru (5°S), due to the presence of Equatorial water, and south of Valparaïso, Chile (33°S), due to the strong presence of lower salinity sub-Antarctic water together with freshwater run-off from rivers entering the bays. The shoreward limit of distribution of *Aequipecten opercularis* in the transition area between the Skagerrak and the Baltic follows closely the 30‰ isohaline and Ursin (1956) considered that queen scallops do not tolerate salinities below 25‰, based on their distribution. This was essentially confirmed by the detailed studies of Paul (1980a) on the salinity-temperature relationships of *A. opercularis*. He found that salinities of 16–28‰ were lethal after a 24 h experimental exposure, depending on the temperature and size of the scallop, with mortalities increasing at the extremes of temperature, and spat having a slightly greater tolerance than larger individuals (Figure 12.8). For the Australian doughboy scallop, *Mimachlamys asperima*, spat are also more tolerant of salinity reductions than the adults (O'Connor and Heasman 1998) while, conversely, spat of *Mizuhopecten yessoensis* appear to be less tolerant than larger individuals. *M. yessoensis* spat is seriously affected by slightly reduced salinities and ciliary activity stops in 75% normal seawater salinity (Yamamoto 1956a), but adults can survive in 60% seawater, although the LT50 in 40% seawater is only 3 hours (Ventilla 1982). In contrast to these open-sea species, *Argopecten irradians*

Figure 12.8. Salinity temperature tolerance of *Aequipecten opercularis*. (a). Regression surfaces for % mortality of three size groups (A. >60 mm; 30-40 mm; 5-10 mm shell height) at different salinity-temperature combinations. Isopleths are produced at intervals of mortality between 10 and 100%. The broken lines represent extrapolations outside the test area; crosses show estimated median lethal salinities. (b). Time to median mortality for the three size groups (A, B, C), plotted as heights above a grid for the various salinity-temperature combinations. Broken lines are extrapolations where median mortality was not reached. (From Paul 1980a).

lives in very shallow bays and estuaries and has been reported in salinities ranging from 10‰ to 38‰ (Belding 1931; Gutsell 1931; Castagna and Chanley 1973; Duggan 1975). This is one of the few scallop species likely to be regularly exposed to very low salinities in its natural habitat during periods of heavy rain and freshwater run-off from the land. Mercaldo and Rhodes (1982) found that adult bay scallops are able to tolerate exposure to low salinities for varying periods of time depending on the temperature. They recorded excellent survival for up to 48 hours in freshwater at 10°C, but not at 24°C, suggesting that this species is better able to withstand exposure to low salinities in the winter months. Nevertheless, Gutsell (1931) reported that periods of heavy freshwater run-off and severe cold weather can cause heavy mortalities in bay scallop populations, and Tettelbach et al. (1985) recorded nearly 100% mortality of northern bay scallops at the highest locations in the Poquonock River, Connecticut, following a very severe rainstorm in June 1982. Similarly, Stockton (1984) states that the formation of a hyposaline lens of seawater under the sea ice during the summer melt is the main cause of mortality of *Adamussium colbecki* in McMurdo Sound, Antarctica.

Various experimental studies of the combined effects of temperature and salinity have also been made on the larval stages of *Argopecten irradians*, both in the U.S.A. (e.g., Tettelbach and Rhodes 1981), and in China (Lin et al. 1989 1991; He and Zhang 1990), where hatchery-reared bay scallops are now the basis of a massive cultivation industry. Tettelbach and Rhodes (1981) showed that normal embryonic development of the northern bay scallop *A. i. irradians* takes place only over a very narrow range of temperature and salinity, from 20–27°C at 25±1‰ salinity. Survival and growth of larvae occur over wider ranges, though temperatures greater than 35°C and salinities less than 10‰ are lethal to all life-history stages. The optimum conditions for larval development of the southern bay scallop, *A. i. concentricus*, occur at rather higher levels of both temperature and salinity. Castagna (1975) gives optimal values of 26–28°C at 28–30‰ and the minimum salinity necessary for survival to the straight-hinged larval stage is 25.5‰. The higher temperature optimum for larval development of *A. i. concentricus* corresponds with a slightly higher temperature at which spawning is initiated in this southern subspecies (Sastry 1963, 1970). These experimental determinations of temperature and salinity tolerance limits, and the optimal requirements of the larvae of the two subspecies, were carried out independently using adult scallops acclimated, conditioned and spawned under different environmental conditions. It is not known if the differences observed are due to genetic or environmental factors. The narrow salinity range for normal larval development of the bay scallop would appear to be an important factor limiting larval dispersal and thereby restricting gene flow between populations in bays and estuaries separated by waters of full salinity. Lin et al. (1989) note that *A. irradians* larvae will not attach when the salinity is below 11.7‰ or above 35‰, and this will also limit their distribution.

Salinity tolerance experiments have also been performed on the larvae of *Chlamys islandica*, which may experience reduced salinities in the fjords of northern Norway (Gruffydd 1976a). These larvae are unable to tolerate salinities much lower than 80‰ seawater for any length of time and possess behavioural responses that prevent them from swimming through vertical salinity gradients into unfavourable conditions. Larvae of

Pecten maximus are unlikely to experience salinity levels much below those of the open sea but are able to tolerate reduced salinities for a short time. Laboratory experiments showed that tidal sinusoidal fluctuations in salinity were much less harmful than steady exposure to reduced salinities, or to abrupt changes in salinity, indicating the special danger of sudden osmotic shocks (Davenport et al. 1975). Recent studies of the effects of reduced salinity on *P. maximus* spat by Christophersen and Strand (2003) found reduced growth, increased mortality and no byssal attachment when salinity was reduced to 20‰. They concluded that locations exposed to salinities below 25‰ for extended periods should be avoided for nursery cultivation of *P. maximus*.

12.3.3.6 Competitors and predators

The ecological role of competitors and predators in determining the local distribution of scallops is poorly understood. Bivalves and other benthic filter feeders may compete for suspended food particles and are thought to filter out and destroy large numbers of planktonic larvae (Thorson 1946; Kristensen 1957); dense assemblages may therefore prevent settlement of larvae in the area (Woodin 1976). This interaction can occur between adults and larvae of the same species, providing a density dependent population regulatory mechanism which could account for the inverse correlations frequently found between settlement density and adult population density for various species of bivalve (Fitch 1965; Hancock 1973; Williams 1980). Such inverse correlations have not been found in any scallop populations, however, and few scallop species would appear to occur in sufficiently high densities for this mechanism to play an important part in regulating the population. Vahl (1982) found evidence for the density dependent control of recruitment to a population of *Chlamys islandica* in Balsfjord, Northern Norway but he considered that this was due to the primary settlement of larvae away from the adult population, followed by a later movement of juveniles on to the adult beds.

Spat and juvenile scallops are very vulnerable to predation by certain crabs, starfish, gastropods and bottom-feeding fish (e.g., Medcof and Bourne 1964; Kim 1969; Buestel and Dao 1979; Elner and Jamieson 1979; Minchin 1981; Volkov et al. 1982; Lake et al. 1987; Lake and McFarlane 1994; Strieb et al. 1995; Arsenault and Himmelman 1996b; Barbeau et al. 1996; Peterson et al. 2001), and in areas of high predator abundance this may well limit scallop distribution. Few attempts have been made to determine predation rates on scallop spat in the natural environment but studies of the mortalities of spat within the confines of collector bags (e.g., Brand et al. 1980; Paul et al. 1981; Thouzeau 1991; Zhang 1996), and of juvenile scallops relayed at higher than normal densities on the seabed (e.g., Volkov et al. 1982; Minchin 1991; Barbeau and Scheibling 1994b; Lake and McFarlane 1994; Barbeau et al. 1996, 1998; Hatcher et al. 1996; Fleury et al. 1997; Barbeau and Caswell 1999; Strand et al. 1999), suggest that predation rates are very variable but can be very high when certain predators are abundant. Eckman (1987) considered that predation was less important than water movements in determining the abundance of juvenile *Argopecten irradians* but numerous subsequent studies have stressed the importance of predation on this species (Prescott 1990; Bricelj et al. 1991; Pohle et al. 1991; Garcia-Esquivel and Bricelj 1993; Strieb et al. 1995; Irlandi et al. 1999;

Peterson et al. 2001). The vulnerability of young scallops to predation obviously varies between species, due to different behavioural and morphological adaptations. This is well illustrated where two scallop species live together in the same habitat. Spat and juveniles of *Placopecten magellanicus* and *Chlamys islandica*, for example, are both preyed upon by the American plaice (*Hippoglossoides platessoides*) and to a lesser extent by the yellowtail flounder (*Limanda ferruginea*) on St. Pierre Bank, but the far greater vulnerability of *Chlamys islandica* is probably due to its greater tendency to remain byssally attached and its weaker swimming escape response (Naidu and Meron 1986). No quantitative data are available for the two common European species but spat of *Pecten maximus* is extremely thin-shelled and fragile compared with *Aequipecten opercularis* of the same size and is likely to be susceptible to a wider range and size of predators. However, in older animals, tethering experiments have shown that the major scallop predators (*Asterias rubens* and *Cancer pagurus*) prey preferentially on *A. opercularis*, rather than *P. maximus*, despite its better swimming escape response (Whittington 1993).

Predation on *Pecten maximus* is reduced when the spat leave sites of byssus attachment and start to recess in the seabed (Buestel and Dao 1978). As scallops get bigger and the shell thickens they become less vulnerable to predation, at least by crabs, which usually feed by breaking the shell open. In experiments on predation of *Placopecten magellanicus* by the rock crab, *Cancer irroratus*, and the American lobster, *Homarus americanus*, Elner and Jamieson (1979) found that preferred prey size increased with predator size, but smaller scallops were particularly vulnerable as predators of all sizes could eat them. Scallops larger than a critical size of about 70 mm shell height were immune to predation by even comparatively large rock crabs and lobsters. Lake et al. (1987) obtained similar results in experiments on predation of *Pecten maximus* by four species of crab. Predation varied with the size of both the crab and the scallop, and they too found that predation was negligible for scallops >70 mm shell height (Figure 12.9). Pennington (1999) confirmed these findings in field trials using tethered scallops and time-lapse photography, backed up by laboratory experiments. However, he found that the common starfish (*Asterias rubens*) was by far the main predator of scallops in the area of the Irish Sea where he carried out his studies. Although starfish appeared to be more flexible than crabs in their ability to deal with larger scallops, the scallops still achieved a size refuge from starfish predation at around 75 mm shell length for starfish of up to 100 mm arm length. Starfish predation was also strongly seasonal, following a bimodal pattern over two years that was associated with the breeding cycle. Interestingly, temperature was not a major factor in determining levels of predation on tethered scallops in this study. Starfish predation showed no correlation with temperature, and while there was a consistent positive association between crab predation and temperature, only one of the statistical tests proved significant. In contrast, Barbeau et al. (1994c) found that both starfish and crab predation on the sea scallop *Placopecten magellanicus* increased significantly with temperature, albeit over a rather greater temperature range. They also found that predation fate by sea stars increased with temperature because of the decreased effectiveness of the scallops' swimming escape response. Barbeau and co-workers have carried out a series of studies on the interactions between juvenile *P. magellanicus* and its predators (Barbeau and Scheibling 1994a, b, c; Barbeau et al. 1994, 1996, 1998), and have

Figure 12.9. Scallop predator-prey size relationships. The total numbers of *Pecten maximus* of different size groups eaten during a 96 h period are plotted in relation to the size of the crab *Cancer pagurus*. The broken line indicates experiments with 3 cm scallops when the time was limited to 48 h. (From Lake et al. 1987).

recently summarised this information into a matrix model to predict scallop survival to commercial size in seabed reseeded operations (Barbeau and Caswell 1999). There is also a very substantial literature on the interactions of the bay scallop, *Argopecten irradians*, and its predators (e.g., Ordzie and Garofalo 1980a, b; Peterson et al. 1989; Prescott 1990; Bricelj et al. 1991; Pohle et al. 1991; Strieb et al. 1995; Bologna and Heck 1999; Irlandi et al. 1999; Powers and Kittinger 2002), and growing information for other

species such as *Chlamys islandica* (Brun 1968; Arsenault and Himmelman 1996b), *Mizuhopecten yessoensis* (Volkov et al. 1982; Kalashnikov 1991; Gabaev and Kolotukhina 1999) and *Argopecten purpuratus* (Wolff and Alarcon 1993; Marahrens 1995; Ortiz and Wolff 2002a, b; Ortiz et al. 2003). Many of the experimental studies of predation on scallops have been based on laboratory studies or tethering experiments, but the relevance of such findings to the situation in the natural environment, where the scallop is free to swim away from the predator, is not always clear (however, see Barbeau and Scheibling 1994b).

Numerous authors have listed the natural predators of each species of scallop but it has been rarely possible to make any quantitative assessment of the mortality rates they generate. Of the few estimates available, most involve predation on adult scallop stocks by large predatory starfish. Thus, Olsen (1955) describes the destruction of a stock of *Pecten fumatus* on one bed, which he considered was primarily due to predation by the large eleven-armed spiny starfish *Coscinasterias calamaria* (Gray). From the decline in scallop densities he estimated that the mortality of scallops amounted to 75–80% over a four-year period. Dickie and Medcof (1963) reviewed the causes of mass mortalities of *Placopecten magellanicus* in the southwestern Gulf of St. Lawrence, estimating mortality as the % of 'cluckers' (empty shells still attached by the hinge) in the total catch. They considered that the largest and most devastating mass mortalities, with up to 80% cluckers, were caused by sudden temperature fluctuations resulting from hydrographic phenomena, but that several of the slower and less spectacular mortalities, with up to 25% cluckers, were caused by predators, either acting alone or, together with temperature debility of the scallops, making them more vulnerable to predation. These higher than usual mortalities were generally associated with an unusual abundance of predators, especially the starfish, *Asterias vulgaris*.

Dickie (1955) described a more precise method of calculating the rate of natural mortality, based on the proportion of cluckers in the catch and the average time for the shell valves to disarticulate in the sea. His results showed that annual natural mortality rates for the same bed were relatively constant from year to year, with average values of 4.5%, 13.8% and 15.7% for three groups of beds in progressively deeper water. Taken over all beds in the Digby area of the Bay of Fundy, he calculated the average annual rate of natural mortality to be about 10% (instantaneous coefficient, $M = 0.1054$). This method has been frequently used in subsequent studies of sea scallop populations on Georges Bank and elsewhere (e.g., Merrill and Posgay 1964; Naidu et al. 1983; Naidu and Cahill 1985; Robinson et al. 1994), and although there is some variability, the estimated values are generally low, in the region of 10–15% ($M = 0.10$ – 0.16). Estimates of natural mortality for other scallops species, made using this or other techniques, have generally produced values of a similar magnitude for unfished populations of long-lived species such as *Pecten maximus* (Baird 1966; Gruffydd 1974a; Brand et al. 1991) and *Chlamys islandica* (Naidu et al. 1982, 1983; Naidu 1988), though values for short-lived species such as *Aequipecten tehuelchus* (Ciocco 1996), *Argopecten gibbus* (Roe et al. 1971; Allen and Costello 1972), *A. irradians* (Belding 1931; Bricelj et al. 1987a), *Comptopallium radula* (Linne) and *Mimachlamys gloriosa* (Reeve) (Lefort 1994), and *Amusium balloti* (Dredge 1985a) are naturally considerably higher. Higher values are also frequently

recorded for exploited populations (e.g., Naidu and Cahill 1984; Naidu 1988; Allison 1993; Allison and Brand 1995) because estimates of natural mortality include scallops damaged but not caught in dredges (Caddy 1968, 1973; Gruffydd 1972). Naidu (1988) comments that, depending on the gear used, 4–8 times as many *Chlamys islandica* die from encounters with fishing gear than through natural causes. While natural mortality is notoriously one of the most difficult population parameters to estimate accurately, and published values show considerable variation from area to area and year to year, there is little evidence to suggest that predation rates are normally high for any scallop species. There are, however, two observations worth noting. Over a 7-year study period, Petersen et al. (2001) recorded an annual virtual extinction of *Argopecten irradians* in one densely occupied seagrass bed, which they showed was due to predation by migrating cownose rays. In an earlier study Brun (1968) found an extremely dense belt of the starfish *Asterias rubens*, about 10 m wide and at least 100 m long, with densities of up to 97 starfish m⁻², moving on a broad front across a bed of *Chlamys islandica*. In front of the *Asterias*, scallop densities were about 60 scallops m⁻², while behind the belt of starfish practically all the scallops were eaten. Such dense aggregations of predators are not normal and this example of an extremely high level of predation would appear to be exceptional. From all available evidence it would seem that predation on adult scallops reduces population density but, for the longer-lived species at least, is not usually sufficiently high to control distribution, except on a very local scale.

Most scallop species, however, respond to contact with their common predators by a swimming escape response (e.g., Buddenbrock 1911; Mellon 1969; Moore and Trueman 1971; Thomas and Gruffydd 1971; Bloom 1975; Ordzie and Garofalo 1980a; Wilkens 1981; McClintock 1983; Dautov and Karpenko 1984; Winter and Hamilton 1985; Pitcher and Butler 1987; Joll 1989; Morton 1996). Swimming by one individual frequently stimulates other scallops nearby and results in mass swimming activity (Chapman et al. 1979; Vahl and Clausen 1980; Minchin and Mathers 1982; Howell and Fraser 1984). Scallops may also be stimulated to swim by other environmental factors, or as an avoidance reaction to fishing gear (Moore and Marshall 1967; Caddy 1968; Gruffydd 1976b; Chapman et al. 1979; Morton 1980; Ansell et al. 1998; Jenkins et al. 2003). In areas of strong current flow, swimming activity can lead to downstream dispersal (Bourne 1964; Moore and Marshall 1967; Gruffydd 1976b; Imai 1980; Posgay 1981; Minchin and Mathers 1982; Melvin et al. 1985; Goshima and Fujiwara 1994; Sakurai and Seto 2000). It is also possible that some species of scallop undergo directed migrations (Allen 1953; Morton 1980; Vahl 1981, 1982; Arsenault et al. 2000). Such movements could account for some of the many reports by fishermen of large commercial scallop stocks disappearing overnight from an area (e.g., Belding 1931; Rees 1957; Rolfe 1973). Whatever the method of stimulation, swimming activity, coupled with downstream dispersal or directed migrations, may therefore play an important part in determining the local distribution of scallop populations. These aspects of scallop behaviour, and their ecological significance, will therefore be considered in more detail.

12.4 SCALLOP BEHAVIOUR - ASPECTS AFFECTING DISTRIBUTION

As might be expected for a group of animals possessing a heavy calcified shell, active swimming behaviour is relatively unusual among the bivalve molluscs, though it has been reported to occur in some members of the families Pectinidae, Amussiidae, Limidae, Solenidae, Solemyidae and Cardiidae (Stanley 1970). Of these, it is best developed in the Pectinidae and the Amussiidae, the only families that swim with the commissure plane in a non-vertical position. Almost all species in these two families have the capacity for free swimming movements for at least part of their life history. Scallops swim by a type of jet propulsion, the powerful water currents for which are generated by rapid adductions that clap the shell valves shut. This is thought to have evolved from the efficient mantle cavity cleansing mechanisms of their byssally attached monomyarian ancestors (Drew 1906; Yonge 1936). Scallops display a range of adaptations associated with swimming and this is reflected in the varying swimming abilities of different species. Post-larval scallops pass through a period of byssal attachment and some species retain the ability to secrete a byssus throughout life. Other species lose the byssus and become free living, using swimming reactions to control their orientation, to recess into the seabed and to escape from predators. The behavioural mechanisms associated with byssus attachment, orientations and movements in post-larval scallops are therefore very important aspects of scallop ecology, affecting both distribution and population dynamics. Behavioural mechanisms associated with larval settlement are also most important but these are considered elsewhere in this book.

12.4.1 Byssus Attachment

The early post-settlement stages of most bivalves secrete a byssus for attachment and a functional byssus persists into the adult in several taxonomic groups, particularly those with a sessile mode of life (Yonge 1962). The neotenous retention of this post-larval structure is thought to have had a profound affect on the evolution of the superfamily Anisomyaria, leading to the suppression of the anterior adductor muscle and the evolution of the monomyarian condition of the Pectinacea (Yonge 1953, 1962; Yonge and Thompson 1976).

Probably all scallops secrete a byssus when young (Verrill 1897) and many species such as *Chlamys islandica* (Gruffydd 1976b, 1978; Vahl and Clausen 1980; Arsenault and Himmelman 1996a), *C. vitrea* (Verrill 1897), *C. furtiva*, *C. tigerina*, *Mimachlamys varia* (Reddiah 1959; Briggs 1983) and *M. asperima* (Young and Martin 1989) retain the ability to form a byssus throughout life. These are generally species of small body size, or those living in areas of strong current flow, and attachment to rocks or other firmly fixed substrates is obviously advantageous for maintaining position in these species. Other scallops cease to form a byssus and live free of attachment on the seabed at some stage in their life history. The large *Pecten maximus* generally loses the byssus soon after metamorphosis and few larger than 15 mm shell length are found attached (Dakin 1909; Eggleston 1962; Mason 1969, 1983; Minchin 1978, 1992; Franklin et al. 1980a). *Mizuhopecten yessoensis* appears to detach at a similar size (Yamamoto 1956a, 1964;

Motoda 1977; Ventilla 1982), while *Pecten novaezelandiae* detaches at a much smaller size of 4–5 mm (Bull 1976). Compared with other scallops the byssus of *Amusium balloti* is a very weak, transient, structure (Wang et al. 2001); it does not appear until after the prodissoconch shell is produced, well after metamorphosis, and is lost when they reach a shell height of 4–5 mm. In *Placopecten magellanicus* (Caddy 1968, 1972; Manuel and Dadswell 1994) and *Aequipecten opercularis* (Soemodihardjo 1974; Paul 1980b), the proportion of the population that is byssally attached at any one time declines with age so that most individuals large enough to be commercially exploited are unattached. *Argopecten gibbus* apparently behaves similarly (Allen 1979), with byssus attachment declining from a shell height of 6–10 mm, but some individuals occasionally attach up to 38 mm. *Argopecten irradians* has a life-span of only 20–26 months and is seldom byssally attached after the first year of life, but individuals of 15–16 months have been observed occasionally fastened to eelgrass (Belding 1931). Byssus attachment inhibits swimming in *Placopecten magellanicus* (Caddy 1972) and *Mimachlamys varia* (Soemodihardjo 1974) but in these, and virtually all other species, contact with predators stimulates attached scallops to release the byssus and make swimming escape responses. The ability to swim efficiently declines in older individuals of some species (Olsen 1955; Caddy 1968, 1972; Gould 1971; Mathers 1976b; Dautov and Karpenko 1984; Parsons and Dadswell 1992; Cheng and DeMont 1996b) but is only lost altogether in the few species, like *Chlamys distorta* or *Hinnites multirugosus*, which become cemented to rock or other hard surfaces later in life (Yonge 1951; Tebble 1966; Soemodihardjo 1974).

Considering the evolutionary significance and great ecological importance of the byssus it is surprising that there have been so few field or laboratory studies of byssus attachment in any scallop species. A number of experiments have been carried out to study the affects of body size and temperature on byssus formation in *Placopecten magellanicus* (Caddy 1972) and *Aequipecten opercularis* (Soemodihardjo 1974; Paul 1980b). In both species, individuals alternate between attached and unattached phases, and the proportion attached at any time decreases progressively with increasing shell size (Figure 12.10). Small scallops are more active in byssus formation than larger scallops: small individuals secrete more byssus threads and re-attach much more rapidly than larger individuals. Thus, Caddy (1972) noted that the time to 50% attachment for *Placopecten* increased from 7 minutes for juveniles of 2–5 mm shell height to 140 minutes for animals larger than 120 mm. The number of byssus threads secreted per scallop per week also increased markedly with temperature but there was no corresponding increase in the proportion attached at the end of the experiment at temperatures above 5°C (Figure 12.11). This suggests that temperature affects the rate of attachment and detachment equally, so that the proportion attached at equilibrium remains independent of temperature over the normal temperature range of the species. For *Aequipecten opercularis* the rate of byssus attachment was highest and least variable at 18°C, declining and becoming more variable at both higher and lower temperatures (Paul 1980b) (Figure 12.12). Byssus formation in this species appears to be extremely sensitive to environmental conditions. Roberts (1973) found that byssogenesis in small *A. opercularis* is twice as sensitive to the insecticide Endosulphan as it is in the mussel *Mytilus edulis* and suggested that byssus attachment could make a very useful and rapid bioassay for potentially toxic compounds.
